As may now be seen, the moment distribution of Fig. 26(b), which underlies the author's concepts, actually cannot occur under any conditions. The author himself is well aware of this fact as may be concluded from his remarks at the end of the discussion of Case 1. However, the writer believes that, contrary to the author's opinion, these disagreements are far from being "secondary considerations." In principle it is scarcely possible to justify basing the safety factor on an entirely fictitious state such as Fig. 26(b), instead of on a clearly defined situation such as Fig. 26(a). The writer agrees fully with the author in that Fig. 26(a) by no means represents an ultimate load; but, if the safety factor or the working load is to be derived from the criterion of permissible deformation (as it should), the real and well-defined situation shown in Fig. 26(f) is by far preferable to the fictitious one in Fig. 26(b). In addition to these fundamental considerations important practical discrepancies result from the author's proposition, as may be shown by the following numerical example: Figs. 26(a), 26(b) and 26(f), respectively, correspond to loads of 10 000, 13 333 and 20 000 lb per ft. A safety factor of, say, 2 would bring the author's working load to 6 667, the writer's value to 10 000 lb per ft. (It should be emphasized that this value of the safety factor, the same as used by the author, is chosen purely for illustration and not as a practical design proposition, the question of finally deciding the actual value of the safety factor being rather complex. Offhand, a factor of 2 seems to be too low if applied to the ultimate load as defined in this paper. In the numerical example the factor of 2, however, had to be maintained in order to obtain results consistent with the author's numerical example.)

Now, suppose that this same beam, instead of consisting of the rectangular bar 6 in. by 2 in., as in the author's example, is made of a standard I-beam 7 in. by $3\frac{3}{4}$ in. by 20 lb, which has the same section modulus $S_e = 12$. According to the author's proposition this I-beam would be attributed the same working load as the rectangular beam, namely 6 667 lb per ft. However, the actual moment transforming the M_m-sections into "plastic hinges" is $M_m = s_y S_p = 30\,000 \times \frac{14.31}{12} = 35\,800$ lb-ft. (For this I-beam, $S_p = 1.193\, S_e = 14.31$.) Hence, the moment distribution at which excessive deformation actually occurs is that of Fig. 26(h). The corresponding uniform load amounts to 15 920 lb per ft and, applying again the same safety factor, the working load would be 7 960 lb per ft. Hence, by the author's method, an actual safety factor of $\frac{20\,000}{6\,667} = 3$ would result for the rectangular beam as compared with $\frac{15\,920}{6\,667} = 2.39$ for the I-beam instead of the nominal safety factor of 2; whereas by the method proposed in this paper the actual safety factor in both cases would be the same, namely the factor selected. It should be emphasized that this definition of the safety factor or working load as related to the load which actually results in excessive deformation has a clearly defined meaning which makes it subject to exact mathematical analysis. The difference in both these concepts follows clearly from Fig. 25(a) which is obtained from actual tests and is in agreement with the theoretical considerations outlined. The author proposes to let both beams, the deflection curves of which are given in Fig. 25(a), carry the same allowable load, disregarding their difference in bearing capacity which is rather obvious from the curves. The writer proposes to determine the working load as depending upon the maximum moment M_m at which excessive deformation begins—that is, essentially, the moments corresponding to Points *b*. The computing work is exactly the same in both cases the only difference being that, for the writer's method, S_p must be known. For standard beams this value, as well as the usual S_e, could be tabulated.

The foregoing discrepancy results from the fundamental fact that once the elastic range of loading is exceeded, the usual section modulus S_e, as based on Fig. 24(a) loses its significance entirely and the only expression that characterizes the further behavior of the beam is S_p, corresponding to Fig. 24(c). The author's method is based entirely on S_e despite the fact that he deals with loads beyond the elastic range; and hence the discrepancies follow logically. The difference between the author's nominal and the actual safety factor would have been even greater if, instead of the I-beam—$S_p : S_e = 19.3$—a beam with, say, $S_p : S_e = 1.10$, had been analyzed.

The writer does not recommend applying the proposed method prematurely to actual design. Many questions must be clarified before a solid basis for a new design theory can be advanced. A number of these problems have presented themselves in the writer's present experimental investigation. For example, the relation between the yield points in bending and in tension, and the influence of the load or strain speed on the yield point seem rather problematical. The questions of residual stresses in rolled sections and of dynamic loading are also so essential, with respect to "limit design," that they should be studied before a new design method is proposed for adoption. Wide possibilities for research are open in this field. It may be noted that similar tendencies toward limit design have gained ground in the field of reinforced concrete beginning from the time in 1931 when Emperger raised the question as to the actual meaning of the ratio *n*. Extensive experimental investigations have been conducted ever since that time and they have not begun to crystallize into a new design theory until now.

The author's important contribution is that he has clearly stated the problem of limit design, thus opening a discussion which, it is to be hoped, will result in useful new ideas in design. Decidedly, the writer shares the author's belief that, after sufficient additional knowledge has been obtained as to the fundamentals, the old design methods, considering the elastic range only, will indeed give way to a broader theory. Nevertheless, they will retain the methods of the theory of elasticity, but will be broadened to include the exact analysis of the actual ultimate strength as defined by permissible deformation.

Francis E. Simpson,[34] M. Am. Soc. C. E. (by letter).—For its pioneering properties, this paper is a valuable contribution to the profession. It should stir the practicing engineer into a realization that perhaps he has become a slave to thinking mechanically in terms of working stresses without giving much heed to either elastic or ductile performance for either structures or parts of structures.

---

[34] Associate Structural and Architectural Engr., Detroit Sewage Disposal Project, Detroit, Mich.

One cannot read this paper critically without becoming fully alive to the fact that, with shifting points of contraflexure and with fixity at the supports being altered in the process of ductile loadings, a beam loaded beyond its elastic limit becomes a most interesting subject of study with all kinds of possibilities in its elastic behavior.

The treatment of frames and of riveted joints brings out many points that are of prime importance, although some of these points are not given the weight they should be given by the majority of practicing engineers. The author states that the practicing engineer seems to have a dread of using stresses approaching the elastic limit, and possibly this is largely true. However, there are instances in which, during construction, parts of structures might necessarily be subjected to rather extreme conditions of loading, and in which designing on the basis of accepted working stresses would result in an uneconomical structure. It is fairly common in such instances for practicing engineers to use working stresses somewhat higher than those ordinarily prescribed. However, even if construction conditions would warrant the use of higher working stresses than is usual, the structure would be designed to carry its design loading with accepted working stresses.

In conclusion, it is appropriate to say that the author should be complimented not only for his splendid paper but for his daring in the suggestion of, what might be termed by some, a slight schism in the realm of thought concerning the theory of elasticity.

JOSEPH A. WISE,[35] M. AM. SOC. C. E. (by letter).—The philosophy upon which the theory of limit design is based appears to be a sound one, but before it can be accepted as a basis for the design of structures, it will require much clarification and perhaps amplification. Of the three dicta proposed, the first one is vague and fails to define a statically indeterminate structure. In one sense, all members, reactions, and restraints function to the same end—that of resisting the applied forces without failing or deforming excessively. The essential characteristic of a statically indeterminate structure is that it has redundant members, reactions, or restraints in excess of the number just sufficient to maintain static equilibrium. The third dictum is a proposition that is not correct. The tower shown in Fig. 15 is at least doubly indeterminate if Member $E\,H$ is considered not acting; yet the failure of two members, such as $E\,H$ and $F\,H$ or $C\,F$ and $D\,F$, would suffice to cause complete collapse instead of the three required by the third dictum. If it should be argued that, with reference to any one bay, this structure is singly indeterminate only, and therefore the failure of two members in one bay constitutes the failure of $n + 1$ members, one need only point out that Members $C\,D$ and $E\,F$ could be chosen as redundants. Thus, it would become necessary to define "bay" so as to include only one of these two members. For more complex structures any such definition would be difficult, if not impossible. As a matter of fact, the third dictum obscures, rather than clarifies, the manner in which structures may fail. In its place, the following is proposed:

---

[35] Associate Prof., Civ. Eng., Univ. of Minnesota, Minneapolis, Minn.

A framed structure will collapse completely when a sufficient number of members have buckled or yielded, so that the remaining part of the structure is statically unstable. The "remaining part" of the structure is defined as that part formed by omitting all members that cannot act to resist any increase in load, because they have buckled or yielded, but including any forces which they supply. It must be noted that even after a member has buckled, due to a compressive force, it may still be available to resist tensile forces, and therefore, whenever the increase in load tends to produce tension in a buckled member, that member should not be omitted in forming the remaining part of the structure.

In the paper, the tacit assumption is made that after a member has buckled it will continue to have the same axial stress until the structure collapses. This is not entirely correct. Fig. 27 shows a pin-connected member subjected to an axial load P. It will be assumed that the member is initially straight, and that the axial load is applied so that the member does not bend until the critical or buckling load is reached. If, now, the distance between the ends is decreased by a distance ΔL, the load P will not change as long as the member remains elastic; that is, no part of it is stressed beyond the yield point. The member will bend, however; the work done by the load will be stored as elastic strain energy of bending. Assuming that the elastic curve is a sine curve

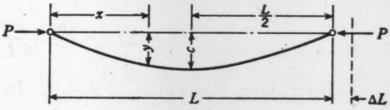

FIG. 27

$$y = c \sin \frac{\pi x}{L} \quad \ldots\ldots (14)$$

a close approximation for ΔL can be obtained as follows:

$$\Delta L = \tfrac{1}{2} \int \left(\frac{dy}{dx} \right)^2 dx = \frac{c^2 \pi^2}{4\,L} \quad \ldots\ldots (15)$$

and

$$c = \frac{2}{\pi} \sqrt{L\,\Delta L} \quad \ldots\ldots (16)$$

The moment at the center will then be

$$M = P\,c \quad \ldots\ldots (17)$$

As long as the material is not stressed beyond the yield point, the axial load will not change appreciably. The small change in axial load, which can be determined by using the exact expression for radius of curvature instead of the approximate value, $\frac{1}{\frac{d^2y}{dx^2}}$, can be neglected in this case.[36] When the member becomes stressed beyond the yield point at the center, however, the moment there cannot be appreciably increased unless the axial load P decreases. As fibers closer to the neutral axis than the extreme fiber reach the yield point, the resisting moment will increase slightly; but it will be sufficiently accurate for this analysis to assume that the moment, M', which exists when the extreme fiber reaches the yield point is the limiting bending moment. Thereafter the axial load will decrease as ΔL and c increase, since

---

[36] "Die Knickfestigkeit," by Rudolf Mayer, Section 4.

$$P = \frac{M'}{c} \qquad (18)$$

Furthermore, as P decreases, the axial length of the member will tend to increase, and this will tend to increase c still further. Calling ΔP the decrease in P, and Δc the increase in c, Equation (18) yields:

$$(P - \Delta P) = \frac{M'}{c + \Delta c} \qquad (19)$$

and including the axial change in length,

$$\Delta L = \frac{(c + \Delta c)^2 \pi^2}{4\,L} - \frac{\Delta P\,L}{A\,E} \qquad (20)$$

Substituting the value of $c + \Delta c$ from Equation (19) in Equation (20):

$$\Delta L = \frac{(M')^2 \pi^2}{4\,L\,(P - \Delta P)^2} - \frac{\Delta P\,L}{A\,E} \qquad (21)$$

Furthermore, as P decreases, the unit axial stress due to it will decrease and thus the section will be able to resist a greater moment when the extreme fiber stress is at the yield point. Calling s the unit stress, in extreme fiber due to moment M', the increased resisting moment will be $M'\left(1 + \frac{\Delta P}{s\,A}\right)$ and Equation (21) becomes:

$$\Delta L = \frac{(M')^2 \pi^2 \left(1 + \frac{\Delta P}{s\,A}\right)^2}{4\,L\,(P - \Delta P)^2} - \frac{\Delta P\,L}{A\,E} \qquad (22)$$

in which A is the area of member. Equation (22) is a cubic, ΔP being the unknown quantity to be determined. It can be solved easily by trial when numerical values are given. Although the axial deformations may be of the order of elastic deformations, the lateral deflections will be much larger. For example, a 3-in. by 3-in. by $\frac{1}{4}$-in. angle, 8 ft long, will have a buckling load (as a pin-ended column) of $P = 16\,100$ lb. It will shorten under this compression, $\frac{16\,100 \times 96}{1.44 \times 30 \times 10^6} = 0.0358$ in. If the ends are caused to move toward each other 0.01 in., the lateral deflection, c, will be $\frac{2}{\pi}\sqrt{96 \times 0.01} = 0.623$ in., or more than 60 times the axial change in length. The moment at the center will be $16\,100 \times 0.623 = 10\,040$ in.-lb. The extreme fiber stress due to this moment will be $\frac{10\,040 \times 1.19}{0.50} = 23\,900$ lb per sq in. at the heel. This stress, combined with the axial compressive stress of $\frac{16\,100}{1.44} = 11\,200$ lb per sq in., would produce a stress of 35 100 lb per sq in., a value close to the yield point of standard structural steel. Any further displacement of the ends of the member toward each other would be accompanied by a rapid increase in lateral deflection and a decrease in axial load. Thus a further decrease in length of 0.01 in. would make $\Delta L = 0.02$ in. Equation (22) becomes,

$$0.02 = \frac{10\,040^2 \times \pi^2 \left(1 + \dfrac{0.42 \times \Delta P}{1.44 \times 23\,900}\right)^2}{4 \times 96\,(16\,100 - \Delta P)^2} - \frac{\Delta P \times 96}{1.44 \times 30 \times 10^6}$$

By trial it will be found that $\Delta P = 5\,700$ lb and

$$c + \Delta c = \frac{M'\left(1 + \dfrac{\Delta P}{A\,s}\right)}{P - \Delta P} = \frac{11\,700}{10\,400} = 1.125 \text{ in.};$$

and $\Delta c = 1.125 - 0.623 = 0.502$ in. Thus, it is seen that, even for axial movements of the order of elastic deformations, the lateral deflections become very large, and the axial load decreases rapidly.

A comparatively simple structure (Fig. 28) will be used to illustrate these principles. Beginning with a load, P, of 200 kips, the stresses in the members, determined by the method of consistent deflections, are shown in Table 1(a), the final step being $X = -\frac{4\,940}{70.8} = -69.9$. The members are assumed to be built so that their slenderness ratios, $\frac{L}{r}$, are at least as small transversely as they are in the plane of the structure. Column (10), Table 1, gives the buckling stress, computed by Euler's formula. If the load is increased to 210 kips, Member $A\,D$ will buckle. At this load the stresses will be those shown in Fig. 29(a). The remaining part of the structure consists of Members $B\,D$ and $C\,D$ only. If a load $P = 1$ lb is applied, the stresses are as shown in Fig. 29(c). Member $C\,D$ has a margin of strength of $76.5 - 73.4 = 3.1$ kips before it

buckles. Thus, if a load of $\frac{3.1}{2.67} = 11.6$ kips is applied at Point *D*, Member *C D* will just buckle, and the added stresses will be as shown in Fig. 29(d). However, this is on the supposition that Member *A D* continues to exert a force of − 41.5 kips. It is necessary to find the horizontal movement of Point *D*. This is done in Table 1(b), which indicates that *D* moves $\frac{28.2 \times 12}{30 \times 10^3} = 0.01128$ in. toward the left. Applying Equation (16), $c = \frac{2}{\pi} \sqrt{432 \times 0.01128} = 1.41$ in. The moment at the center would be $41.5 \times 1.41 = 58.5$ in-kips. The extreme fiber stress due to this bending moment would be $\frac{58\,500}{8.6} = 6\,800$ lb per sq in.

The axial stress would produce $\frac{41\,500}{4.78} = 8\,680$ lb per sq in., or the combined stress would be 15 480 lb per sq in., which is well within the yield point. The total stresses for the frame at this stage are shown in Fig. 29(b).

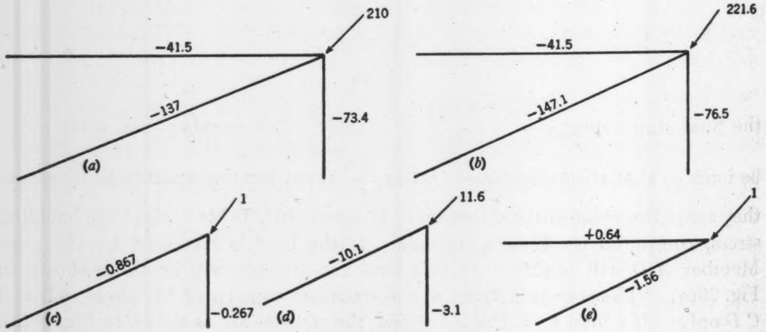

FIG. 29

The next step will be to consider Members $A\ D$ and $B\ D$ as the remaining structure after Member $C\ D$ buckles. Member $A\ D$ is included since an increase in load will tend to induce tension in that member. Fig. 29(e) shows the stresses due to $P = 1$ lb. The very smallest increase in load will permit Member $A\ D$ to transfer the elastic strain energy stored in it, due to the previous movement at Point D of 0.01128 in., into Member $C\ D$. Since no appreciable change in load or stress is assumed to occur during this transfer, Member $B\ D$ will merely rotate about Point B, guiding Point D along a line at right angles to Member $B\ D$. Therefore Point D moves vertically a distance equal to $\frac{12}{5} \times 0.01128 = 0.0271$ in. Again applying Equation (16):

$$c = \frac{2}{\pi} \sqrt{318 \times 0.0271} = 1.87 \text{ in.};$$

and, the moment at the center would be $76\,500 \times 1.87 = 143\,000$ in-lb. The maximum stress due to combined bending and axial stress would be $\frac{143\,000}{8.6} + \frac{76\,500}{4.78} = 32\,630$ lb per sq in., compression. Assuming a yield point of 33 000 lb per sq in., Member $B\ D$ has a margin of strength of 198.9 kips left at this stage. It would require an added load of $\frac{198.9}{1.56} = 127.6$ kips to produce this stress. However, since Member $C\ D$ has practically reached its yield point, the load in it will now tend to decrease as Point D moves downward, and therefore the stress in Member $B\ D$ will be increased by this effect. Thus, it is obvious that the structure will not sustain an added load of 127.6 kips.

Proceeding by trial, first add a load of 10 kips; the added stresses will be $+ 6.4$ in Member $A\ D$ and $- 15.6$ in Member $B\ D$, assuming no unloading from Member $C\ D$. The vertical deflection of Point D will be 0.1149 in. ($= \Delta L$). For this case, ΔP will be 41 500 lb, the stress in Member $A\ D$ is changed from $+ 99.5$ to $+ 58.0$, and the stress in Member $B\ D$ is changed to $- 254.9$ kips. This change, in turn, will cause Point D to deflect further, and the cycle will be repeated. It will be found that only about 5 kips can be added before collapse occurs; hence the limit load for this structure is about 226.6 kips. Thus, the structure will carry more than the limit load as determined from Members $A\ D$ and $C\ D$; and, also all three members buckle before final collapse occurs.

If a similar, step-by-step analysis is applied to the tower in Fig. 15, it will be found that Member $C\ F$ will buckle first, when the load at the top of the tower reaches 33.5 kips. It will be found that an additional load of 8 kips at the top will then cause the buckling of Member $D\ F$, and therefore the structure will collapse at a total load of 41.5 kips, instead of the 60 kips for which it was designed. Thus, it can be seen that the procedure proposed by the author is not valid unless checked by a step-by-step analysis of the behavior of the structure as a whole; and, that it is not correct to assume that a member will continue to have the same stress after it has buckled as it had at the buckling point.

One other phase of the subject should be emphasized. The dead load of a structure is not ordinarily likely to be increased appreciably, and only the increase in live load can lead to a failure due to over-load. By present methods of design, structures with large ratios of dead load to live load, such as reinforced concrete structures, are penalized in comparison with others (such as steel structures). Under limit design, concrete structures would probably have proportionately greater reductions in sizes of members than would steel structures.

There is also an inconsistency in the basic paper, in that the author states that, in the theory of limit design, the emphasis is to be shifted from "stress" to "permissible deformation." Nevertheless, the paper proceeds to discuss the stresses chiefly, a procedure which it had previously condemned. As a matter of fact it does not matter whether one uses the limiting deformation or the stress at which it occurs, as the criterion for the strength of a member, except in cases where two-dimensional or three-dimensional states of stress occur. Then the deformations depend on all stresses and not on the stress in the direction of the deformation alone. Therefore, the subject should be separated into two parts: (1) Structures with uni-axial states of stress; and, (2) structures with bi-axial or tri-axial states of stress. For the first type this discussion is pertinent; for the second type, the question of the controlling factor at failure will depend upon the material; for brittle materials generally, the deformations will control; and, for ductile materials, a shearing stress which is also a function of the maximum tensile stress, as indicated by the Guest-Hancock, or Mohr theory of failure, will control.

ALFRED FREUDENTHAL,[37] ASSOC. M. AM. SOC. C. E. (by letter).—Very ably the author has presented a picture of the behavior of steel structures stressed above the yield limit. A comprehensive treatment of the theory of limit design based on the ductility of steel is destined to meet with serious difficulties as, at the present time, the main features of the theory of plasticity are in a state of flux. Under the stipulated conditions and the assumptions made, the author's point of view may be justified. However, the writer believes that these conditions are encountered in only a restricted number of cases in practice and that, in general, the assumptions are not valid. Furthermore, a number of important influences have been insufficiently considered (or not at all); and this might involve fundamental changes in the conception of the theory of limit design.

(1) The author asserts that the capacity load of an n-time statically indeterminate structure is reached after $(n + 1)$ members have all reached their elastic or buckling limit strength. With regard to the danger of buckling, this statement, in its general form, is quite a dangerous one because the author's conviction that "in the consideration of compression members the logic is essentially the same as that applied to tension members" does not seem to be based on evidence. Furthermore, the author is not at liberty to choose a buckling formula. The introduction of Euler's formula is not subject to "preference"; its validity is purely a question of whether buckling occurs before the yield point is reached or after it has been exceeded.

---

[37] Res. Engr., Marine Trust, Tel-Aviv Port, Tel-Aviv, Palestine; Lecturer on Bridge Engineering, Hebrew Institute of Technology, Haifa, Palestine.

As the author states, the load-deformation relationship after the buckling has begun is of particular importance to the entire problem. This relationship (see Fig. 30) differs essentially in the cases of elastic and plastic buckling.[38]

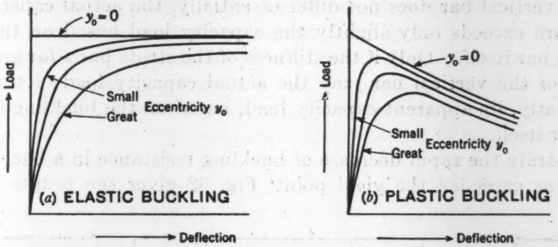

FIG. 30.—ELASTIC AND PLASTIC BUCKLING; LOAD-DEFLECTION CURVE FOR VARIOUS ECCENTRICITIES

Thus, the behavior of statically indeterminate structures is materially affected by the type of buckling involved.

To make this fact clear, the behavior of the structure in Fig. 31 may be considered. With an increasing load, P, the capacity load of the structure is reached in different ways, depending on the proportion of stresses in, and the buckling stiffness of, the struts and the vertical bar. According to the theory of elasticity the force acting in the vertical bar has the value

$$X = \frac{P}{1 + 2\,\dfrac{A_s}{A_v}\sin^3\phi} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (23)$$

in which A_v and A_s, respectively, are the cross-section areas of the members indicated. For $\phi = 30°$ and $A_s = A_v$, the force in the vertical bar is $X_v = 0.8\,P$; and the force in the struts, $X_s = 0.2\,P$. Because of this difference between stresses in the elastic state, below the stability limit, the members of the structure cannot be stressed to capacity simultaneously. The following are the different possibilities of reaching the capacity load of the structure:

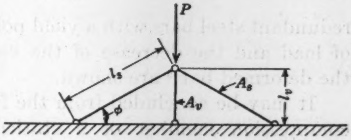

FIG. 31.—A STATICALLY INDETERMINATE SYSTEM

(a) The buckling limit of the vertical bar may be exceeded before the stress $X_s = \dfrac{X_v}{A_v}$ reaches the yield point. Under increasing lateral buckling deflection of the vertical bar and almost constant buckling resistance (see Fig. 30(a)), the forces in the struts increase gradually, until their elastic buckling limit (and, with it, the capacity load of the entire structure) is reached. Hence, the structure collapses under stresses which are, in all members, below the yield point.

(b) The buckling limit of the vertical bar may be reached after the stress has exceeded the yield point. Referring to Fig. 30(b), the resistance of the bar decreases considerably with increasing lateral deflection, thus involving a rapid increase of the forces acting in the struts. Subsequently, their buckling limit is reached and the structure collapses. If the buckling resistance of struts and vertical bar does not differ essentially, the actual capacity load of the structure exceeds only slightly the capacity load based on the buckling limit of the bar itself. Only if the stiffness of the struts has a far greater value than that of the vertical bar may the actual capacity load of the structure exceed, greatly, its apparent capacity load, based on the buckling limit of the vertical bar itself.

---

[38] "Plasticity," by A. Nadai, McGraw-Hill Book Co., Inc., New York, N. Y., 1931.

To illustrate the rapid decrease of buckling resistance in a bar,[39] the stress of which has exceeded the yield point, Fig. 32 gives the results of tests on

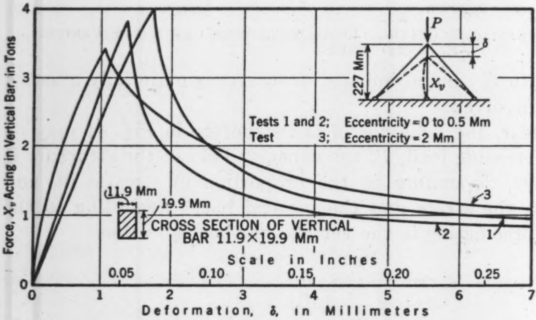

FIG. 32.—RELATION BETWEEN FORCE AND DEFORMATION FOR VARIOUS DEGREES OF ECCENTRICITY.

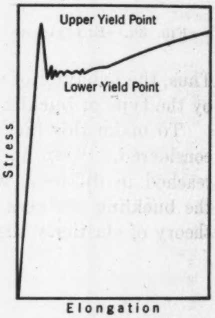

FIG. 33.—STRESS ELONGATION CURVE OF STEEL IN TENSION

redundant steel bars with a yield point of 33 500 lb per sq in. The relationship of load and the decrease of the vertical distance between the end points of the deformed bar[39] are shown.

It may be concluded from the foregoing that the behavior of a redundant compression member of a statically indeterminate structure, stressed to capacity under continually increasing load, differs essentially from the behavior of a tension member, under similar conditions. The "fear of buckling" which, as the author remarks, "appears deeply ingrained" is fully justified not only from the point of view of the theory of elasticity but even more from the point of view of the theory of (plastic) limit design. Hence, Bleich's statement[6] concerning compression members is correct: The theory of limit design must never be applied to trusses. The statement by Professor Kist,[13] however, that "the engineer need not apply the theory of elasticity in order to assign values for statically indeterminate quantities" is exaggerated; it applies only to a very limited number of structures; and, in its general form, it is open to strong criticism.

---

[39] "Three Contributions on the Loading Question of Statically Indeterminate Steel Trusses," by E. Chwalla, Publications of the International Assoc. for Bridge and Structural Engineering, Zurich, Switzerland, Vol. 2, 1933–1934.

Until now one fact has not been considered. In practice, compression members do not consist of bars of rectangular sections, but of angles, channels, and joists. The stability limit of such sections is generally not reached gradually as assumed theoretically for rectangular sections. The particular form of the section almost always causes elastic or plastic buckling, with simultaneous torsion, bending, or premature buckling of the flanges, and with an almost instantaneous, abrupt loss of the buckling resistance. This phenomenon leads to a load-deformation relationship of plastic buckling which is far more unfavorable with respect to the influence of the resistance of the compressed member on the capacity load of the structure than the load-deformation relationship assumed in the theory of limit design.

(2) The behavior of compression members in trusses, as assumed in the paper, is only one of the features that makes the general conclusions advanced by the author open to criticism. It will be shown that the assumption underlying the theory of limit design for members acting under bending stresses cannot be fully endorsed, either.

The assumption of an ideal plastic behavior of the material, according to Fig. 2, has proved to be valid only for special kinds of steel and under particular forms of loading. During the past few years the foregoing assumption has been strongly opposed by various writers. Their objections are based on a considerable number of tests which have shown that the existence of an upper yield point (Fig. 33), as well as the apparent rise of the yield stress, due to non-uniform distribution of stresses over the sections (as in the case of bending), causes an elastic behavior of the structure far above the limit assumed on the basis of a theory developed from the ideal plastic behavior of the material. The upper yield point is only partly influenced by the quality of the material and depends to a great extent on the velocity of the loading.[40] For slowly applied loads the ratio of upper and lower yield point will be greater than for rapidly applied loads. This is explained by the occurrence of the upper yield point, which may be considered as a "retardation of yield" similar to the phenomenon of the retardation of the boiling point of liquids. Instantaneously applied loads cause the upper yield point to drop.

Furthermore, it has been proved by tests that in many cases the maximum stresses in beams under loads have reached values considerably exceeding the yield point of the material established in the tension test. This "raised yield point" may amount to 1.2 to 1.7 of the yield point, in pure tension, depending on the cross-section of the beam. If the load is increased still further the cross-section reaches the plastic state instantaneously over its full height, and the stresses show a sharp drop from the upper yield point to the value of the lower yield point. Local instability (as, for example, buckling of the flanges, bending or torsional deformation) is often the result. The assumption of an ideal plastic behavior of the material, as proposed by the author, therefore, has only a restricted application.

(3) On the other hand in the design of bridges fatigue is far more important than plasticity. The occurrence of pulsating and reversed stresses will always

---

[40] "General Theory of Plasticity," by A. Freudenthal, Rept. I, 1, Second International Congress for Bridge and Structural Engineering, Berlin, Germany, 1936.

demand the design of bridges on the basis of the endurance limit of the material. Such a design will require a higher factor of safety than would be required by (plastic) limit design; therefore its use for such cases would always be imperative.

The endurance of a structure is particularly influenced by the form of the connections. It is diminished by notch action in gusset-plates as well as in welds, and by the thermal residual stresses in and around welds. One may conclude, therefore, that even under conditions favoring the application of the theory of limit design in the proposed form, the connections between the members will always represent weak and critical points where the validity of a design based on the ductility of the material alone may become questionable.

(4) The general conclusions to be reached on the basis of all the aforementioned facts are that the theory of limit design, in the form presented by the author, is applicable but to an extremely limited number of structures under permanent or slowly changing loads. It must not be applied to trusses even under fixed or slowly changing loads. In the design of bridges, where the endurance limit of the material, and the notch-action in the connections are the dominant factors, its application would not be justified.

Although the structural engineer is certain to be aware of the limits of the theory of elasticity, it does not seem justifiable to recommend its abandonment in favor of an unqualified acceptance of the theory of (plastic) limit design. It is certainly appropriate to endeavor to develop a theory which most closely fits the facts; but the theory of limit design, as presented by the author, can scarcely be regarded as fulfilling this requirement. Therefore, within certain limits, the theory of elasticity will remain the basic theory for the structural engineer, provided that the factor of safety is established on the basis of a thorough understanding of the actual behavior of the structure. This may involve the revision, and even the abandonment, of the current conception of stress.

The author is to be congratulated, sincerely, for having stressed this important fact.

HANS H. BLEICH,[41] ESQ. (by letter).—In his very instructive paper demonstrating the practical use of the theory of limit design the author extends its application to trusses. Such extension is not permissible because it is necessary that all compression members be so proportioned that the stresses induced will never reach the buckling limit. It is true that, if a compression member is loaded to its buckling capacity, a slight buckling will appear, the effect being to shorten the bar so that some other bar will begin to carry the load of the compression member. The extent of the buckling is limited, however, and must be very small. If the bar bends beyond a certain limit it can carry only a part of the full buckling load of the straight bar. An investigation of this permissible limit shows that, generally, compression members cannot be shortened as much as is required by the theory of limit design.

---

[41] Dr. Ing., Vienna, Germany.

For simplicity, consider only the top panel of Fig. 15(*a*). According to the force diagram (Fig. 15(*f*)), the forces in Bars *c* and *d* are assumed to be 35 000 lb and 50 000 lb, respectively. It is required to compute the shortening of Bar *c* in order to produce these total stresses in Bars *c* and *d*.

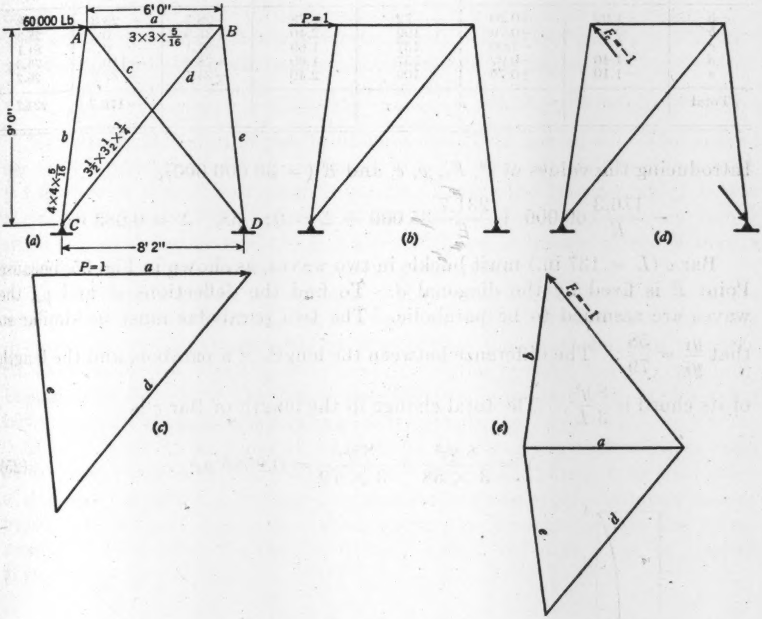

FIG. 34

Fig. 34(*c*) and 34(*e*) are the force diagrams for this panel, subjected to the loads $P = 1$ and $F_c = -1$. In Table 2 the total stresses induced by Load $P = 1$ are F_a' and F_b'; and, the total stresses induced by Load $F_c = -1$ are F_a'' and F_b''. The change in the length *A–D* caused by the force $P = 1$ is $\Delta_P = \sum \frac{F\,F''\,l}{E\,A}$; and, the change produced by the force $F_c = -1$ is $\Delta_F = \sum \frac{(F'')^2\,l}{E\,A}$ (see Columns (7) and (8), Table 2). Thus, it is found that $\Delta_P = \frac{176.3}{E}$ and $\Delta_F = \frac{231.7}{E}$. If the change in the length of Bar *c*, caused by the buckling of this bar, is called Δ, the general equation for the force F_c is

$$P\,\Delta_P + F_c\,\Delta_c + \Delta = 0 \quad \text{.................. (24)}$$

TABLE 2.—COMPUTATION OF STRESSES IN THE TOP PANEL OF FIG. 15(*a*)

Bar (see Fig. 34(*a*)) (1)	Total stress, F', due to a load $P=1$ (2)	Total stress, F'', due to a load $F_c=1$ (3)	Length of member, L, in inches (4)	Area, A, in square inches (5)	$\frac{F'' L}{A}$ (6)	$F' \frac{F'' L}{A}$ (7)	$F'' \frac{F'' L}{A}$ (8)
a	−1.00	+0.70	72	1.78	+28.3	− 28.3	19.8
b	0	+0.79	109	2.40	+35.9	0	28.3
c	0	−1.00	137	1.69	−81.1	0	81.1
d	+1.40	−0.97	137	1.69	−78.6	−110.1	76.3
e	−1.10	+0.76	109	2.40	+34.5	− 37.9	26.2
Total	....	....	....	....	....	−176.3	231.7

Introducing the values of P, F_c, p, c, and E (= 30 000 000),

$$-\frac{176.3}{E}\,60\,000 + \frac{231.7}{E}\,35\,000 + \Delta = 0; \quad \text{or,} \quad \Delta = 0.083 \text{ in.}$$

Bar c (L = 137 in.) must buckle in two waves, as shown in Fig. 35, because Point E is fixed by the diagonal d. To find the deflections y_1 and y_2, the waves are assumed to be parabolic. The two parabolas must be similar so that $\frac{y_1}{y_2} = \frac{58}{79}$. The difference between the length of a parabola and the length of its chord is $\frac{8\,y^2}{3\,L}$. The total change in the length of Bar c is:

$$\Delta = \frac{8\,y_1^2}{3 \times 58} + \frac{8\,y_2^2}{3 \times 79} = 0.0586\,y_2^2 \ldots\ldots\ldots\ldots\ldots (25)$$

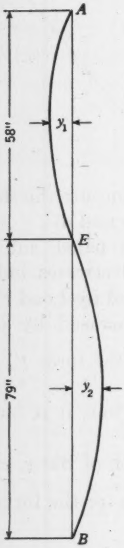

FIG. 35

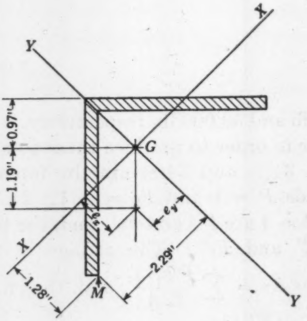

FIG. 36

The value of Δ necessary to produce the given stresses was found to be 0.083 in.; and the corresponding deflection was $y_2 = \sqrt{\frac{0.083}{0.0586}} = 1.19$ in.

Fig. 36 shows the cross-section of Bar *c* with its center of gravity, *G*, and the eccentricities, e_x and e_y, of the load with respect to the *X* and *Y* axes. The eccentricity is $e_x = e_y = 0.707\ y_2 = 0.83$ in.; the area of the cross-section is $A = 1.69$ sq in.; the moments of inertia are $I_x = 0.83$ in.^{4} and $I_y = 3.22$ in.^{4}; and, the greatest stress will occur in the corner of the angle, *M*:

$$s = \frac{35\,000}{1.69} + \frac{35\,000 \times 0.83}{0.83} 1.28 + \frac{35\,000 \times 0.83}{3.22} 2.29 = 86\,000 \text{ lb per sq in.}$$

This stress exceeds the elastic limit of 30 000 lb per sq in. The curved bar with a deflection of 1.19 in. is not able to carry the full buckling load. It follows that the entire system is unable to carry the load for which it was originally designed. The assumed redistribution of the load between Bars *c* and *d* can never occur because Bar *c* would have to buckle so much that it would lose about two-thirds of its buckling strength.

This example leads to the conclusion that either all compression members must be safe against buckling or, if a bar can be loaded beyond its buckling strength, the truss system without this critical bar must be able to carry the entire load (the small loading capacity of the buckled bar is neglected). Engineers made use of the latter possibility a long time ago in designing trusses with crossed diagonals in the center panels.

If the theory of limit design, limited by the foregoing statement, is used for the design of trusses, there will be no economical advantage over the theory of elasticity, except in a few special cases such as the aforementioned case of trusses with crossed diagonals. It was with this conviction that the writer stated,[9] in 1932, that the theory of limit design had better not be applied to trusses.

ALFRED S. NILES,[42] ASSOC. M. AM. SOC. C. E. (by letter).—The interesting question as to the proper method of determining the factor of safety of an engineering structure is reviewed by the publication of this paper. In practice the engineer has to choose between two classes of design methods. At present many structural engineers use what may be termed "working stress methods" in which they compute the stresses that would be developed by the maximum probable loads and so proportion the structure that these stresses do not exceed the "allowable working stresses" of the materials used. These allowable working stresses are obtained by dividing the pertinent "ultimate stresses" by the desired factor of safety. The alternative is to use what may be termed an "ultimate stress method" in which the maximum probable load is multiplied by the desired factor of safety to obtain the "ultimate load." The stresses that would be produced by this ultimate load are then computed and the structure so proportioned that these stresses do not exceed the appropriate ultimate stresses. The method of "limit design" described in the paper is obviously in the latter class. The author may protest against describing it as a method of comparing stresses, since he claims that emphasis should be placed on deformations rather than on stresses; but it is difficult for the writer to understand how the deformations can be determined without first computing the stresses that cause them.

---

[42] Prof., Aeronautic Eng., Leland Stanford Junior Univ., Aero Laboratory, Stanford Univ., Stanford University, Calif.

The essential difference between the two basic design methods can be shown most clearly by the aid of a numerical example. Suppose it is desired to determine the adequacy of a 1-in. square bar of steel, 40 in. long, to carry simultaneously an axial compression of 6 250 lb and a uniformly distributed transverse load of 5.5 lb per in. It will be assumed that the bending moment at each end is zero, that Young's modulus is 30 000 000 lb per sq in., and that the compression yield point of the material, 36 000 lb per sq in., is the appropriate ultimate stress. For the 1-in. square cross-section the moment of inertia, I, is $\frac{1}{12}$ and the section modulus, $\frac{I}{y}$, is $\frac{1}{6}$. The formula[43] for the maximum bending moment resulting from the assumed loading is

$$M_{\max} = w j^2 \left[1 - \sec\left(\frac{L}{2j}\right) \right] \quad\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

in which: w is the transverse load; L is the length of the member, $j = \sqrt{\frac{EI}{P}}$; E is Young's modulus; I is the moment of inertia of the cross-section; and, P is the axial compression.

If the desired factor of safety is 2.0 and the working stress method is used, the maximum permissible value for the total unit stress, $f = \frac{P}{A} + \frac{My}{I}$, will be $\frac{36\,000}{2} = 18\,000$ lb per sq in. Using Equation (26) to determine the imposed stress, $j^2 = \frac{EI}{P} = \frac{30\,000\,000}{12 \times 6\,250} = 400$; $j = 20$ in.; $\frac{L}{2j} = 1.00$; $\cos\left(\frac{L}{2j}\right) = 0.5403$; and, $1 - \sec\left(\frac{L}{2j}\right) = 0.8508$. Then $M_{\max} = 5.5 \times 400 \times 0.8508 = 1\,872$ in-lb. The total imposed stress is therefore $f = \frac{P}{A} + \frac{My}{I} = \frac{6\,250}{1} + 1\,872 \times 6 = 17\,482$ lb per sq in. Thus, according to this method of computation the member in question would be adequate, the desired factor of safety having been provided with a margin of about 3 per cent.

Suppose, however, the investigation were made by the ultimate stress method. The analysis would then be made for an axial load of 12 500 lb acting in conjunction with a transverse load of 11.0 lb per in., whereas the allowable total stress would be 36 000 lb per sq in. From these data, $j^2 = 200$; $j = 14.14$ in.; $\cos\left(\frac{L}{2j}\right) = 0.15615$; and, $1 - \sec\left(\frac{L}{2j}\right) = 5.4041$. Then $M_{\max}$

---

[43] "Airplane Structures," by Alfred S. Niles and Joseph S. Newell, John Wiley & Sons, Inc., New York, N. Y., 1938, Vol. II, Second Edition, p. 98.

= 11 889 in-lb, and the maximum unit stress becomes $f = 83\ 834$ lb per sq in., which is more than twice the allowable value of 36 000 lb per sq in.

This example is an extreme one, but it illustrates the difference between the two basic methods and shows that the decision as to whether to use a working stress or an ultimate stress method of analysis may have a great influence on the adopted design sizes. Using the working stress method the 1-in. square rod was found adequate by a small margin; using the ultimate stress method, however, it was found inadequate by a large margin.

The ultimate stresses that may be used in either type of procedure are of various kinds. Some, like the ultimate tensile strength, are the maximum true stresses that can be resisted without causing fracture of the material. Others, like the yield point, are stresses at which plastic flow and permanent set begin to be excessive. Still others, like the stresses used in column design, are those at which a member becomes unstable, due either to elastic deformation, plastic flow, or a combination of the two. Finally, there are ultimate stresses in common use, like the modulus of rupture, which are not true stresses but merely convenient numbers which represent, indirectly, the maximum load that a member can carry.

Before an intelligent selection can be made of a general method of design and the ultimate stresses to be utilized, it is necessary to consider in more detail what is to be recognized as "failure." The most serious type of failure is that which occurs when a structure becomes unstable and collapses. Simple examples of this are failures of a truss due to the elastic buckling of a long slender strut or to a tension member being pulled away from its anchorage. In some structures, however, instability and collapse may be preceded by excessive deformations due to plastic flow, and such conditions are properly to be regarded as constituting a type of failure. The elongation of a bolt hole due to over-load is an example of this type, and may be termed "plastic failure" to distinguish it from the previously mentioned "instability failure."

In order to obtain the most economical designs consistent with safety, both types of failure must be considered, and it is advisable to use different ultimate stresses and factors of safety for the two types. This has been the normal practice in airplane design for several years, and it has proved to be quite satisfactory.

The factor of safety that should be provided for any specific part of a structure depends on both the type of failure it is intended to prevent and the type of ultimate stress used. For plastic failure, the yield point is the most appropriate ultimate stress, and since experience has indicated that a factor of safety of 1.00 is sufficient, that is the value specified by the Civil Aeronautics Authority. This requirement is governing only where it would take a much larger load to cause collapse than that needed to produce excessive plastic flow. It is also equivalent to the author's proposal that a design be checked to insure that the maximum probable load will not cause stresses in excess of the yield point. The justification for such a low factor of safety against plastic failure is that, even if the assumed maximum probable load should be exceeded in service, the result would not be disastrous but would merely cause some deformations of the structure which normally could be repaired satisfactorily.

The factor of safety to be provided against instability failure, however, should exceed 1.00 since otherwise a load in excess of the assumed maximum that is probable would be likely to cause a disastrous collapse. The desirable magnitude of this factor of safety depends on many influences, including the importance of weight economy, the reliability and precision of the methods of analysis, the uniformity of materials used, and the quality of workmanship to be expected. In aeronautical work the importance of weight economy is so great that a factor of 1.50 is the usual value, but larger values are specified for members and types of construction for which experience has shown it to be difficult to predict the strength with precision.

For the benefit of the engineer who may consider these aeronautical factors of safety to be dangerously low, the writer believes a few explanatory remarks are in order. It must first be remembered that these factors are not applied to the loads encountered in normal flying, but only to the most severe loads likely to be encountered in strenuous maneuvers or very rough air. The factors provided against the loads encountered in normal flight are several times the foregoing values. Secondly, the maximum load to which an airplane can be subjected in flight can be predicted with more confidence than the weight of the heaviest truck that may try to cross a new highway bridge. In the third place, airplane designers have the benefit of many static tests to destruction to guide them, but full-scale destruction tests of bridges and buildings are most unusual. As a result, the airplane designer can be more confident that he actually has provided a factor of safety of 1.5 than many designers of other structures can be that they have provided their nominal 2.0 or more. Finally, the fact should be mentioned that major structural failures of airplanes are very rare, and aeronautical engineers therefore consider that, although the factors of safety they use are very low, they are adequate if proper care and skill are used in developing their designs.

The factor of safety may be defined as either the ratio of the ultimate stress to the stress produced by the maximum probable load, or as the ratio of the load that would cause failure to the maximum probable load. The use of a working-stress method of design implies the use of the former definition, whereas the use of an ultimate-stress method implies the latter. If internal stresses remained strictly proportional to external loads right up to the point of failure, it would make no difference which definition and method of design were used. In actual structures, however, this proportionality up to failure is the exception rather than the rule, and usually the second definition results in a lower value for the factor of safety for a given design than the former.

A common type of structural member in which the internal stresses are not directly proportional to the external loads is the "beam-column," or member subjected to combined axial compression and transverse bending loads. If such a member is subjected to a loading that produces a maximum internal stress equal to half the ultimate, the external loads can be increased until the maximum unit stress is doubled before failure takes place. This result will be obtained, however, before the external loads have been doubled. Thus, when the factor of safety in terms of unit stresses is 2.00, it would be less than 2.00 in terms of external loads. In situations of this character it appears much more reasonable to define the factor of safety in terms of load than in terms of stress. A logical consequence is that an ultimate-stress method rather than a working-stress method should be used in design.

An additional reason for this practice is that the use of an ultimate-stress method permits a designer to check the reliability of his methods of analysis by static tests to destruction. If a structure is designed to a factor of safety of 1.50 by an ultimate-stress method, the static test will show, clearly and directly, whether or not the desired end has been achieved. However, if it is designed to a factor of safety of 1.50 by a working-stress method, it is practically impossible to use destruction tests to determine whether the desired end has been achieved. In such a case it may be that the tension members should not fail until the structure is subjected to 1.50 times the design load, whereas some compression members may be expected to fail under 1.35 times the design load. If the compression members failed under 1.38 times the design load, their adequacy would have been established, but the adequacy of the tension members would remain undetermined. Any attempt to check designs made by a working-stress method by means of static tests to destruction involves a mass of interpretative computations which are of doubtful validity. Thus, if tests are to be made (and they are clearly desirable if economically feasible), the designs must be made by an ultimate-stress method.

In much structural design the deviation of the internal stresses from strict proportionality to the external loads is small, the factors of safety provided are relatively large, and weight saving is of minor importance. As a result, working-stress methods of design have given satisfactory results. In airplane design these conditions have not obtained. Types of construction are in common use in which the deviations of the internal stresses from strict proportionality to external loads are large, factors of safety are relatively small, and weight saving is of the utmost importance. As a consequence of these conditions the airplane designers have, for a long time, been accustomed to using ultimate-stress methods of design.

Some types of structural members, notably struts of moderate slenderness, become unstable as soon as the yield point stress is reached, or the load that can be added after the yield point has been reached is negligible. For the design of such members against instability failure the yield point of the material is a logical ultimate stress to be used in practice. Other types of members, such as rectangular beams, must be subjected to considerable increments of load after the yield point has been reached before they collapse. The writer is in complete accord with the author in protesting against the use of the yield point as the ultimate stress in the design of such parts.

In designing to obtain a desired factor of safety against collapse, particularly when it is desired to take advantage of any capacity of the structure to carry a larger load than the minimum necessary to produce elastic buckling or plastic flow in some of its elements, the methods used to compute the imposed stresses must be considered in the selection of the corresponding ultimate stresses. The most common practice is to compute the stresses that would be caused by the ultimate design load under the assumption that the stress distribution would be the same as if the material remained elastic, even though it is recognized that the resulting computed stresses are fictitious. This is the sensible thing to do whenever the corresponding ultimate stresses can be suitably determined. An example is a beam subjected to simple bending. At maximum load the actual maximum unit stress in such a beam is difficult to determine, but it is relatively easy to determine a "modulus of rupture," assuming that the formula $f = \frac{M\,y}{I}$ remains valid.

With some other types of structure this procedure is inapplicable, as some parts will buckle elastically under a fraction of the load needed to cause failure of the whole. In most cases of elastic buckling of a redundant member, the buckled member continues to carry the load which caused the buckling but refuses to carry any more when additional external load is imposed on the structure. Thus, when a plate girder with a very thin web is subjected to simple bending under low loads, the shear on the girder is transmitted primarily by shear stresses in the web. These shear stresses may be resolved into diagonal tensile and compressive stresses acting at right angles to each other. As the external load is increased, the diagonal compressions cause the web to buckle into a series of waves or wrinkles parallel to the diagonal tensile stresses. If the web were not provided with suitable vertical stiffeners, this buckling would result in instability and collapse of the entire beam. When the stiffeners are provided, however, increases in shear can be carried by increased diagonal tensions in the web, compression in the vertical stiffeners, and suitable stresses in the chord members, and that is just what takes place. If the buckling of the web into wrinkles were considered to represent failure, the ultimate strength of the girder would often be only a small fraction of the load actually required to cause collapse. The airplane designer recognizes this fact and uses the actual load-carrying capacity of the girder as its ultimate strength for use in design. In computing the stresses present when the girder becomes unstable the more conservative method is to disregard the diagonal compressive stresses that are actually carried across the wrinkles. Some airplane designers, however, prefer to include these compressive stresses as part of the resistance of the girder to load, and to count on this resistance in design.

A similar situation is found in the panels of thin sheet metal with longitudinal stiffeners that are frequently used in the construction of airplane fuselages. In this construction the parts of the sheet midway between stiffeners buckle elastically under relatively low loads. As the loads increase, the width of the buckled sheet also increases, increments of load being carried by the stiffeners and the parts of sheet adjacent to them. Eventually only the stiffeners are able to provide resistance to increments of load, and when the critical stresses are reached in the stiffeners, the entire structure collapses. One might say that the proper method of design would be to consider only the strength of those parts of the combination that are still accepting increases in load when the ultimate load is approached in computing the strength of the panel. This is not the practice, however, as the parts that have buckled elastically are still carrying some of the load, and the carrying capacity of those parts is included in computing the strength of the unit. The magnitude of this supporting effect of elements that will have buckled elastically is often difficult to predict, and the question is the subject of much research, both theoretical and experimental.

Although it is common practice in airplane design to take cognizance of the changes in stress distribution due to elastic buckling in computing ultimate loads, it is not usual to do the same with respect to changes in stress distribution caused by plastic flow. There would appear to be no valid objection to doing this if the detailed procedure employed were logically sound. The author offers certain suggestions along this line, but some of his detailed proposals are open to serious question.

In his first case the author assumes that after the elastic-limit stress has been reached at the supports of a beam fixed at both ends, the section at each support acts as a pin joint. Thus, if the load of 10 000 lb per ft produces a moment of 30 000 ft-lb and that moment produces the yield-point stress in the outer fibers, the resisting moment at the support under a load of 13 333 lb per ft will also be only 30 000 ft-lb. This is far from being true. Under 10 000 lb per ft there will be linear variation of stress over the cross-section, and only the outermost fibers will be subjected to the yield point stress. Under any additional load the deformation of the end sections will increase, more and more fibers will be subjected to the yield point stress, and the resisting moment will increase. The result will be that the movement of the points of inflection toward the supports will be less than that estimated by the author. From this it might be argued that the author's method is conservative, and that may be true, but before applying it in practice a more careful study of all the factors involved should be made.

In his second to fourth cases the author makes a study of the effect of unloading and repetition of load, but omits any consideration of the distribution over the cross-section of the residual strains and internal stresses that he assumes to exist. His conclusions may be useful in stimulating research but should not be used as a basis of design until the distribution of such strains and stresses has been more thoroughly investigated.

Another factor that should be given careful study before adopting the author's detailed procedure for cases involving plastic flow is the shape of the stress-strain diagram of the material used. Ordinary structural steel has a definite yield point, but this is not true of structural aluminum alloys, stainless steel, or many of the high-strength steels that are coming into use. This means that an important factor underlying the author's proposals is lacking when applied to the materials used where economy of weight is an important consideration. His theory may be modified to apply to these materials without definite yield points, but for these, as well as for structural steel, it requires more extensive digestion than is indicated in the paper.

A. Floris,[44] Esq. (by letter).—When the stresses in some parts of the statically indeterminate structure reach the plastic limit of the material, other less stressed parts come into play, thus causing a better distribution of stress. This equalization, commonly called "self help" of the redundant structure, is the thesis of the author's paper on limit design.

In some instances, this equalization occurs quite naturally, without the aid of the plastic property of the material. In a beam fixed at both ends and carrying a vertical concentrated load in the middle of the span, for example, the bending moments at both ends and in the middle are equal and of opposite signs. Within the elastic limit of the material, therefore, the ratio of positive and negative moments is 1 : 1. Such cases are rare, however, and, in general, recourse must be taken to the plastic behavior of the material, if an equalization of stress is to be achieved.

In this thought provoking paper the author treats the fixed-end beam exclusively. Unfortunately, the use of this structural element is rather restricted in practice. Continuous structures—beams (which are very common) as well as rigid frames—have been ignored. No doubt, this is a very serious omission.

Steel structures of these types can be analyzed conveniently by means of factors that take care of the moment reduction caused by the plastic flow of the material. As soon as this stage is reached, imperfect hinges are formed in places where the bending moments have their greatest value, thus relieving the strains by redistribution. The ensuing greater freedom of motion in the structure can easily be counterbalanced by the remaining numerous constraints of the manifold redundant structures.[45] In the light of the theory of plasticity, therefore, highly redundant systems are safer against the effect of unforeseen emergencies, including settlements of supports and destructive earthquakes. This is quite the opposite of the results obtained by the elastic theory.

Although the theory of plasticity is readily applicable to steel structures, in the case of reinforced concrete the problem is more complicated. In this composite material, only the steel reinforcement has a well-defined yield point; the concrete is a brittle material. However, as G. von Kazinczy has shown experimentally,[46] the compressive strength of concrete remains constant during the initial yielding of steel. On the basis of this fact it is possible to develop a theory of stress analysis and design.

In statically determinate framed structures it is always possible to stress all bars to the limit; but it is never possible in internally redundant frames, if the dimensioning is done in accordance with the elastic theory. In such structures of n-fold static indeterminacy, it is possible to stress all except n bars to the limit. These n bars constitute, so to speak, the reserve strength of the frame. Consequently, the greater the number of redundants in relation to the remaining bars, the greater will be the economic advantages by applying the theory of plasticity.[47]

[46] "Die Plastizität des Eisenbetons," by G. von Kazinczy, *Beton u. Eisen*, 1933, p. 74.

Framed structures designed either by the elastic or plastic theory are perfectly safe. The advantages gained by the use of the theory of plasticity are economy of material and simplicity of analysis. Thus, the most economical solution can be found with the least effort.

Redundant compression bars cannot be included in the analysis of the structure for the following reasons: When the buckling strength is reached, the resistance of the bar ceases and the supporting capacity of the redundant frame is reached almost instantaneously. This has been demonstrated by several tests.[48] The factor of safety is much larger for compression than for tension bars. The latter can sustain considerably plastic deformations without greatly endangering the safety of the structure. However, as soon as the former reach their buckling strength, the frame will collapse immediately. The redundant tension bars having a smaller factor of safety will reach the plastic stage earlier than the redundant compression bars with a greater factor of safety.

For example, by removing the redundant bar of a frame, statically indeterminate in the first degree, in which the tension reaches the permissible stress first, a force is applied in the direction of this bar equal to the allowable unit tensile stress multiplied by an arbitrarily chosen cross-section. This force, combined with the external loads, determines the axial forces of the bars, which later are dimensioned on the basis of the allowable unit stress. In designing a framed structure in accordance with the theory of plasticity, therefore, the permissible unit stress is not eliminated. The method proposed in this paper, to design framed structures for an over-load capacity in order to avoid the use of the allowable unit stresses, is objectionable because of the foregoing reason concerning factors of safety.

In the following a simple example will illustrate the points in question: The cantilever frame composed of Bars *ab*, *ac*, and *ad*, Fig. 37 has a span of 6.5 ft, carries a load of 75.0 kips and is statically indeterminate in the first degree. All double angles are $\frac{3}{8}$ in., back to back, and all bars have welded connections.

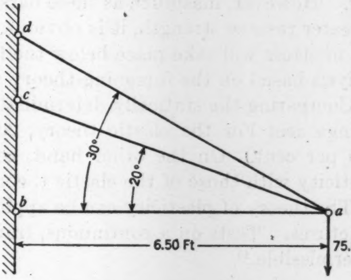

FIG. 37.—CANTILEVER FRAME

By using the elastic theory, the axial force in any of the three bars can be chosen as the redundant quantity. In the present case the axial force of Bar *ad* is taken as the redundant. Inasmuch as the frame has one degree of statical indeterminacy, the stresses in one bar only cannot be utilized completely. This is Bar *ac*, as the results of the elastic theory have shown. After repeated trials, the most economical solution has been determined, as given in Table 3, in which the solution of the statically determinate frame is included for the purpose of comparison.

According to the results of the elastic theory, Bar *ad* is the only tension member in the frame. Even in a different combination of sections and possible reversal of sign in Bar *ac*, the tension in Bar *ad* will always reach the permissible stress first. In all cases Bar *ab* is under compression and consequently is excluded from consideration. For this reason only Bar *ad* can be subjected to plastic deformation.

TABLE 3.—VARIOUS SOLUTIONS OF THE CANTILEVER FRAME IN FIGURE 37

Bar	STATICS			ELASTICITY			PLASTICITY		
	Dimensions, in inches	Axial force, in kips*	Unit stress, in kips per square inch*	Dimensions, in inches	Axial force, in kips*	Unit stress, in kips per square inch*	Dimensions, in inches	Axial force, in kips*	Unit stress, in kips per square inch*
ad	....	....	....	2—4×3½×⅝	+154.0	+17.9	2—4×4×½	+135.0	+18.0
ac	2—7×3½×⅝	+219.0	+17.8	2—2½×2½×½	− 8.0	− 3.4	2½×½	+ 22.0	+17.6
ab	2—6×6×⅝	−206.0	−14.5	2—4×4×⅝	−125.0	−13.6	2—4×4×⅝	−137.0	−14.8

* Plus denotes tension and minus denotes compression.

By removing and replacing Bar *ad* by a tensile force, equal to the product of allowable tensile stress by an arbitrarily chosen sectional area, the axial forces in the other bars are determined by statics. Selecting for Bar *ad* a smaller section than that given by the elastic theory, it is obvious that the stress in this bar will be nearer to the plastic deformation than in all other bars. However, inasmuch as these bars, in accordance with the design, possess a greater reserve strength, it is obvious that the force distribution or equalization of stress will take place below the limit of safety. The data of the frame analysis based on the foregoing theory are also given in Table 3.

Comparing the statically determinate frame with the redundant frame, the savings are: For the elastic theory, 20.3%, and for the theory of plasticity, 29.5 per cent. On the other hand, comparing the results of the theory of plasticity with those of the elastic theory, the saving is 11.5 per cent.

The theory of plasticity can be applied also to externally redundant framed structures. Tests on a continuous, framed beam have demonstrated that this is permissible.[49]

L. H. NISHKIAN,[50] M. AM. SOC. C. E. (by letter).—Many experienced structural engineers have long recognized that, generally, in a redundant structure those structural elements best able to resist any given set of forces will ultimately carry the major part of the load if the structure is sufficiently loaded. (The term "redundant structure" as used herein does not necessarily mean a structure with more than the minimum number of members. A continuous beam or other indeterminate structure where all members or all

parts of the same member are not working at equal efficiencies would be redundant within the present meaning.) In other words, within the elastic limit, load distribution is based on the principle of relative rigidities, whereas, beyond the elastic limit, the distribution would tend to approach a basis of relative strengths. Although the general principle is recognized by some and occasionally is used by a few, this idea has not been presented in American engineering literature, at least not quantitatively. Very ably, the paper deals with this subject and its logical corollaries.

FIG. 39.—DETAIL 1, FIG. 38

In January, 1939, the writer observed an accidental condition in a cofferdam which, under the usual assumptions of design, should have failed but did not. Fig. 38 shows this coffer-dam as designed and built. Fig. 38(b) shows the loads on the wales resulting from the water pressure when pumped out to a level just below the lower wale.

During the driving of the sheet-piling, apparently the corner of Wale *A*, Fig. 38, was caught by the lower end of the pile with the result that one end was pushed down, twisted, and entirely disengaged from Wale *B*. In other words, the sheet-piling caught at Point *a*, Fig. 39; the lower Wale *A* bent down; and the connection at Point *c* was broken loose, removing all support at the end of Wale *B*. Wale *A* was so connected to Wale *B* that it acted as a column to take the end reaction of Wale *B*—about 185 kips. This accident was not noticed until the water was pumped down to the level below the lower wales—about Elevation − 20 ft. With the water at this level, the load on the wales at Level 1 was more than 95% of the maximum load when fully pumped out. With Wale *A* pushed out of the way, Wale *B* had no end support and acted as a cantilever from the next strut—about 15.5 ft from the end.

Checking the capability of Wale *B* to carry this load as a cantilever, it was found to be entirely inadequate, even when using stresses of 36 kips per sq in. The capacity of the sheet-piling then was checked, assuming it to span from the top wale to the tremie concrete and assuming the lower end fixed. This also was inadequate at 36 kips per sq in. Adding the maximum carrying capacity of the sheet-pile and Wale *B*, acting as a cantilever, both being stressed to the elastic limit, it was found that the resulting combined carrying capacity was still less than the water pressure acting on the coffer-dam. By all the ordinary rules, Wale *B* and the sheet-piling should have collapsed. Measurements at the end of Wale *B* showed a horizontal deflection in excess of the elastic deflection of either the sheet-piling or the cantilever, Wale *B*, each stressed to the elastic limit of the steel. This corroborated the previous computation that the steel

Fig. 40.—Loading and Moment Diagrams (Back Pressure of Water in Cofferdam Neglected)

would be stressed beyond its elastic limit, but did not explain why it did not fail.

An analysis was then made along lines similar to those suggested by the author. If the first two sheet-piles continued to yield until the negative moment (never more than the resisting moment of the section at the elastic limit) at the tremie support became equal to the positive moment in the sheet-piling, and the remaining load was taken by Wale *B* as a cantilever, it was found that a balance would be struck although both the sheet-piling and the wale would be strained beyond their elastic limits. Figs. 39 and 40 show the moments resulting under this assumption. Fig. 40(*b*) demonstrates that a resisting moment of 192 ft-kips, within the elastic limit, is necessary to resist the loading given in Fig. 40(*a*). Even if a greater efficiency is effected by exceeding the elastic limit (see Fig. 40(*c*)), it is still necessary that the sheet-piling have a resisting moment of 130 ft-kips at the elastic limit to avoid failure. Since the resisting moment at the elastic limit is only 115 ft-kips, a reaction of 3 040 lb (as indicated in Fig. 40(*d*)) must be developed at Wale *B*, Fig. 38, to prevent deflection to the point of failure. Line *AB*, Fig. 40(*d*), was determined by the resisting moment at the elastic limit of the sheet-piling (115 ft-kips). Line *AC* was drawn in such a manner that the moment intercepted at the center was also 115 ft-kips. This can be produced only by a reaction of 3 040 lb at Wale *B*.

In Fig. 39 the third sheet-pile from the end is shown reacting 93 kips on Wale *B*. Actually the elastic deflection of Wale *B* at this point will reduce this 93 kips and increase the 23 750-lb reaction at the second sheet-pile. An examination of the coffer-dam showed that the first three sheet-piles had been noticeably deflected, whereas the fourth was quite straight.

The author has presented a worth-while paper. A careful study of the ideas presented will lead to a more realistic understanding of the actual behavior of structures.

F. G. ERIC PETERSON,[51] ESQ. (by letter).—Inasmuch as it focuses attention on possible revisions of design theory now used in engineering practice, this paper is a valuable one. Considerable study and much experimental work is necessary before the "Theory of Limit Design" can be accepted in actual design. The writer appreciates the new field of research opened by Professor Van den Broek's treatise.

The following discussion is confined to the "theory" as applied to beams and gives the results of tests applied to a beam resting on three supports. A test was made by the writer to determine the actual behavior of a continuous beam on three supports when subjected to the action of two concentrated loads as shown in Fig. 41(*a*). The position of the concentrated loads was such that the moment over the center support, as determined by the principle of continuity applied to an elastic structure, was a maximum. Before cutting the beam to the desired length a short piece was sawed out and submitted to the usual tensile test, the results of which were 38 600 lb per sq in. for the yield point and 61 700 lb per sq in. for the ultimate strength.

---

[51] Instructor in Mathematics and Mechanics, Univ. of Minnesota, Minneapolis, Minn.

Referring to Fig. 42: For stresses below the elastic limit the moment over the center support and the moment under the concentrated loads will equal, respectively:

$$M_1 = -0.192\frac{PL}{2}\ldots\ldots\ldots\ldots\ldots\ldots(27a)$$

and

$$M_2 = 0.133\frac{PL}{2}\ldots\ldots\ldots\ldots\ldots\ldots(27b)$$

From the foregoing yield point stress, and the structural properties of the beam, it is found that the maximum resisting moment of the beam with no stresses exceeding the yield point is equal to 7 720 ft-lb, corresponding to a total load of 13 400 lb, or 6 700 lb on each span.

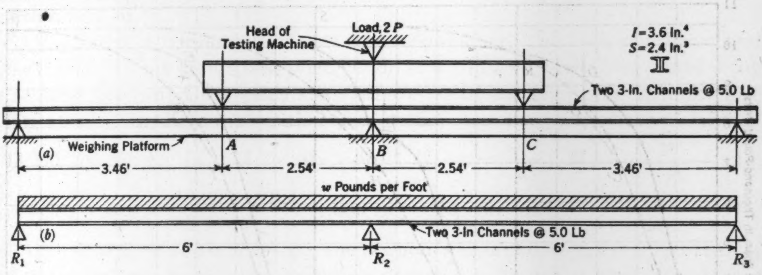

FIG. 41

According to Professor Van den Broek's theory the moment over the center support would reach a certain maximum and then remain constant at this value with increasing load until the moment under the loads reached this same value, at which time the beam would fail. From the test made by the writer this does not seem to be the case. Professor Van den Broek acknowledged the fact that the negative moments at the supports of his fixed beam increased somewhat as the load is increased. The writer believes from his test that as the load is increased the positive moment under the load and the negative moment at the supports increases appreciably until the failure load is reached. Of course, after the extreme fiber at a section has reached the yield point the resisting moment at this section increases more slowly but will not reach a constant value until failure defined as continued deflection without increase in load occurs. At this point the critical sections act as elastic hinges.

A separate test was made on a simple beam 5 ft long of the same cross-section as the beam continuous over three supports. When a single concentrated load at mid-span reached a value of 7 800 lb the beam continued to deflect without appreciable increase in load. This gives a resisting moment of $M = \frac{PL}{4} = 9\,750$ ft-lb and would seem to indicate a stress of $s = \frac{9\,750 \times 12}{2.4} = 48\,750$ lb. Of course, this is not a true stress since the outer fibers were stressed beyond the yield point somewhat before failure occurred; but it is comparable to the usual modulus of rupture. Almost all of the cross-section is at the yield point stress but has not begun to approach the ultimate strength.

Assuming that the moment over the center support and also under the loads could reach this value of 9 750 ft-lb before deflection without increase in load, the load on each span could be 10 500 lb or the total load 21 000 lb. This value is in close agreement with the test made as the maximum load was found to be somewhat more than 20 000 lb.

The beam was loaded as indicated in Fig. 41(*a*). At each load increment strain gage readings were taken, four at each of the three sections *A*, *B*, and *C*, using a 2-in. gage. The graphs of Fig. 42 show the strains at the extreme fibers corresponding to the loads. The solid lines show the measured strains; and they appear to be somewhat smaller than those computed from the loads indicated by the testing machine, probably attributable to the fact that the strain gage records average strains over a distance which has a varying bending moment. Furthermore, the gage points were placed at the edge of the flanges and therefore a little closer to the neutral axis than the extreme fibers. The vertical lines at *D*, *E*, and *F*, Fig. 42, indicate the yield point strain (approximately). The line *L H* is the computed load strain line at Section *B* up to a load of 6 700 lb. At Point *H* the extreme fibers at Section *B* have reached the yield point. Lines *K G* and *M I* represent the load strain line for Sections *A* and *C*, respectively. If the moment at Section *B* remained constant when the extreme fiber reached the yield point the load strain curve at Points *A* and *C*, Fig. 41(*a*), would be as *G D* and *I Q*, respectively, up to the yield point strain of the extreme fibers at these sections. However, since Section *B* gives an increasing resisting moment beyond this point the strains at Sections *A* and *C* would increase less rapidly and would follow curves similar to *G R S* and *I T V* instead. Points *S* and *V*, Fig. 42, are on a horizontal line at the theoretical maximum load and are obtained by neglecting a section 0.5 in. above and below

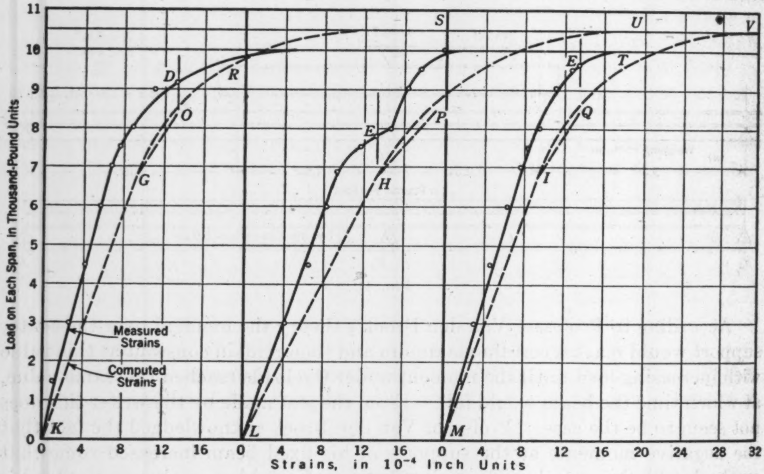

FIG. 42

the neutral axis. This section has a moment of inertia about one one-hundredth of the total section.

Applying a factor of safety of 2, the maximum total load would be 10 500 lb (calculated) or, the load P on each span would be 5 250 lb. Note that the load necessary to cause a yield-point fiber stress at the center support is 13 400 lb or about one-third higher. Allowing a maximum fiber stress of 18 000 lb per sq in. (which is common practice) the allowable total load would be $P = \frac{2 M_1}{0.192 L} = 6\,250$ lb, or 3 125 lb on each span. This load allows a factor of safety of about 2 for a yield point stress of 38 600 lb but a factor of safety of 3.68 for the structure as a whole. It would thus seem that for statically indeterminate structures that the theory of limit design shows that higher loads can be used with safety.

The Case of a Uniform Load Over Three Supports.—The ordinary theory and the theory of limit design is applied herein to a uniformly distributed load using the same beam and the same span lengths as in the preceding example (see Fig. 41(*b*)). In the ordinary theory of design, assuming a maximum stress of 18 000 lb per sq in.: $M_1 = M_3 = 0$; $4 M_2 = -\frac{w l^2}{2}$; $M_2 = -\frac{w l^2}{8}$; and, $w = \frac{8 M_2}{l^2} = \frac{8 \times 18\,000 \times 2.4}{36 \times 12} = 800$ lb per ft, safe load.

In the theory of limit design, the section was found to resist 9 750 ft-lb of moment before appreciable deflection occurred. Assuming that M_2 reaches this value, the minimum load per foot necessary to cause the same positive moment at some point in the beam, is obtained as follows: $R_1 = \frac{\frac{1}{2} w l^2 - 9\,750}{l} = 3 w - 1\,625$. The moment at any point in the beam is

$$M = R_1 x - \frac{w x^2}{2} = (3 w - 1\,625)\, x - \frac{w x^2}{2} \ldots\ldots\ldots (27c)$$

Setting Equation (27*c*) equal to 9 750 ft-lb, $w = \frac{19\,500 + 3\,250\, x}{6 x - x^2}$; $\frac{dw}{dx} = \frac{3\,250\,(6 x - x^2) - (19\,500 + 3\,250\, x)\,(6 - 2 x)}{(6 x - x^2)^2} = 0$; and, $x = 6\,(\sqrt{2} - 1)$ gives a minimum value of $w = 3\,160$ lb. The value of $x = l\,(\sqrt{2} - 1)$ found herein holds for any maximum resisting moment of any beam of two spans of equal length on three supports.

Applying a factor of safety of 2 to this load results in a safe load of 1 580 lb per ft. The maximum deflection with this load is approximately 0.12 in. Since this load is almost sufficient to cause yield-point stress over the center support the practicing engineer might wish to reduce it. However, even if it is reduced to 1 200 lb it is still 50% greater than the value obtained by the customary method. Note that, in this method, the concept of stress did not enter.

The writer wishes to acknowledge the suggestions and assistance of Paul Andersen. Assoc. M. Am. Soc. C. E., in the preparation of this discussion.

E. S. Fabian,[52] Assoc. M. Am. Soc. C. E. (by letter).—The essential functional requirements of any structure are: (1) That it be strong enough to withstand the application of the loads of specified magnitude; and (2) that under the application of these loads it exhibit a certain degree of resistance to deformation and thus maintain its geometric integrity. Strength and stiffness within the prescribed limits are the basic considerations of any design theory whether applied to individual members or to entire structures. Since the indices of both the strength and the stiffness of any structural member are expressed in terms of its dimensions and the physical properties of the material of which it is made, strength and stiffness of a structural member are definitely related. Parametric equations for strength and for stiffness can be written in each case and, by varying the parameters, simultaneous values can be obtained from which curves can be drawn. From these curves the functional relation of strength and stiffness can be ascertained conveniently. It is the character of this function that determines whether the principle of superposition (see heading "Introduction") applies.

To admit the application of the principle of superposition to a structure, the following conditions must be postulated:

(1) The character of the impressed load must not change as the load is increased;

(2) The geometric configuration of the structure must not appreciably change with the increase in the load;

(3) As the Load P changes, the axial (and bending) loads on each member of the structure must change proportionally to the change in Load P;

(4) As the loads on the members change, with the change in Load P, the unit stresses and total deformations must remain proportional to the loads; and,

(5) The total deformations of the various members—tensile, flexural, and compressive—must be of the same order.

Conditions (1) and (2) must also apply to each member in the structure.

The author's predication (see heading "Introduction") "that a structure will fail only when as many members, or restraints, as the structure has redundants plus one, are loaded to their capacity strength" and his third dictum (heading "Theory") are unquestionably valid within the limits of the operation of the principle of superposition; so is his design procedure as illustrated by the application to the design of a tower. As the writer understands it, this design procedure consists of three main steps which can be outlined as follows: (*a*) Apply an over-stress factor, n, to the design load of a structure; (*b*) on the basis of this "capacity" load, draw a continuous force diagram, and if it closes, it may be regarded as satisfactory; and (*c*) assume the dimensions of one member, in conformance to the force diagram, and proportion the neighboring members in relation to it as indicated by the force diagram.

To design a structure in this manner on the basis of the configuration of the structure when it is unloaded, is to assume that this configuration will not change appreciably while the capacity load is gradually diminished to zero value and then gradually increased back to the $\frac{1}{n}$th portion of its capacity value. To assume that when this is accomplished each member (which was designed for its capacity load) will be subjected to $\frac{1}{n}$th portion of its capacity load, is to postulate that throughout the process of unloading and partial loading the loads on each member, its unit-stresses and its total deformations, are constantly proportional to Load P. It must be assumed that

---

[52] Asst. Prof. of Civ. Eng., Univ. of Tennessee, Knoxville, Tenn.

$$\frac{dP'}{dP} = \frac{ds}{dP} = \frac{d\Delta}{dP} = \text{a constant} \ldots\ldots\ldots\ldots\ldots (28)$$

in which P = the total load on the structure; P' = the load on a member; s = the unit stress in the member; and Δ = the total deformation of the member. This assumption is equivalent to stating that the structure must act as a "unit"; that is, the structure acts as a whole and is analogous to a single member of like character. However, a condition of this nature can be approximated only in extremely rigid structures, in which the members at each joint can be assumed to be of virtually equivalent rigidities, giving the structure a character of homogeneity. Their axial deformations, whether tensile, compressive, or flexural, can be assumed to be very small, and the resultant displacements of the joints are negligible. The application of the principle of superposition can be admitted and the design can be made on the basis of static equilibrium. However, due attention to permissible joint displacements and consequent deformations has resulted, in the case of suspension bridges, in considerable economy of design.[53] Similar economy can undoubtedly be shown for other structures.

The stiffness of a structure as a whole is a function of the ratio of the loads (dead and live) that the structure must carry to its over-all dimensions. In certain types of structures this ratio is rather small and, if the deflections are of no consequence and are permitted to be large, the design results in a "light" type of structure. The behavior of these structures under applied loads is very dissimilar to the behavior of structures of a heavy or rigid type. This latter type will display a degree of elastic stability under any condition of stress intensity in its members up to the yield point. (In certain cases elastic stability may persist when the stresses in some members are beyond the yield point.) The light type of structure, however, may reach a condition of neutral equilibrium, presenting the danger of failure by buckling, when the magnitude of stresses in its members is considerably below the elastic limit. This dissimilarity of action can be explained only by the supposition that the ratios of stresses to deformations are not the same in the two types. In a light structure the deformations proceed at a greater rate than the stresses, or, stated briefly, the principle of superposition does not apply. Such light structures are very sensitive to the effects of the eccentricities and nonsymmetries at the joints, and their light members will often be subjected to a combination of axial and lateral loads.

---

[53] *Transactions*, Am. Soc. C. E., Vol. 91 (1927), p. 894.

When applied to whole structures, the principle of superposition must be postulated from the proportionality of total deformations to the applied loads. In the manner indicated in the first paragraph of this discussion, it can be shown that, in general, the relation between the capacity loads of various structural members and their stiffnesses is not a straight-line function. It is an asymptotic curve, similar in many respects to Euler's curve, the asymptotic part of which is in the range of low slenderness ratios (that is, high stiffness) of the members. Assuming this part of the curve to be a straight line it can be seen that the axial deformations of heavy, stiff members, whether they are subjected to tensile, flexural, or compressive loads, will be of the same order. Experiments validate this assumption. As the curve recedes from its asymptote in the direction of higher slenderness ratios, the rapid change in the slope of tangents to the curve indicates that such similarity in axial deformations in slender members cannot be assumed. In other words, the principle of superposition cannot be applied to structures joined by slender members of heterogeneous character. For similar reasons the principle of superposition cannot be applied to slender members subjected to the simultaneous action of heterogeneous loads such as compressive and bending loads. It can be shown that under these conditions the load-resisting function of a member, as regards lateral loads, is approximately proportional to 1 minus the ratio of the applied axial load to the capacity axial load.[54] By analogy a similar proportionality can be postulated for the structure as a whole.

Where the conditions are such that the law of superposition cannot be applied, the distribution of loads to various members cannot be made on the basis of simple statical conditions—namely, the force diagram—but it must be made on the basis of Maxwell's equations—that is, by the "influence-line" method. Herein, to the writer's mind, lies the anomaly of the author's thesis. Although Professor Van den Broek emphasizes the importance of deformations, the force diagram is the key to his analysis; although he holds the deformations of a structure to be of prime importance, he criticizes, as unsound, the very methods of analysis which are based on considerations of deflections.

Just how far a theory postulated upon the law of superposition applies to structures to which the law does not apply, and within what limits of deviation from this law, is not a problem pertinent to this discussion of limit design. A theory pushed beyond its rational limitations becomes an hypothesis. That the standard specifications, formulas and methods used in structural design are open to questioning cannot be denied. They have been developed with reference to certain types of structures and to meet specific problems. Their application to the light type of structures, particularly of the highly indeterminate character, may be questioned on the grounds of economy. To this end, the author has rendered a valuable service in raising the problem. The theory of limit design is undoubtedly applicable in certain cases. With modifications, particularly with reference to compression members and the factor of safety, perhaps its application could be extended. The limits of its application and the extent of the necessary modifications can be ascertained, however, only by considerable additional analysis and by checks against the methods that experience has shown to be reliable and economical.

---

[54] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 882.

A. A. Eremin,[55] Assoc. M. Am. Soc. C. E. (by letter).—In the last half of the Nineteenth Century various theories of failures in structural materials were developed. However an extensive theoretical and experimental study is needed to apply them to the computation of the stability of structures. Development of the limit-design method based on the theory of failure may be found in various practical rules applied to the design of structures.

The most common application of the limit-design method is in the design of foundations for statically indeterminate structures. It is well known that foundation deformations do not follow Hooke's law. Therefore, in each case the designer establishes the maximum possible displacement of the footings, and computes the factor of stability of the structures in carrying a given loading. An interesting illustration of the practical application of limit-design computation is in determination of the critical loading carried by a group of piles under spread footings. The piles with the least bearing resistance settle faster and approach a uniform distribution of loading on all piles in the group, which determines the limit-design loading. Computation of the critical loading carried by structural details, such as hinges or pins, is often based on practical rules established by the principles of the limit-design method. Likewise, in the design of rivet connections the principles of the limit design may be considered. Interesting computations of the distribution of deformations in rivets were shown by the late G. F. Swain, Past-President and Hon. M. Am. Soc. C. E.[56] An application of the limit-design method to the computation of the critical loading in statically indeterminate structures has been demonstrated by Professor Timoshenko.[57] Professor Timoshenko has shown that strains in a member with stresses above the elastic limit may be expressed by the average modulus of elasticity, and a critical loading carried by the structure may be computed with the equations based on the elastic theory.

It is unfortunate that the author, in Cases 1 and 3, has considered the beams with constant moments of inertia. In important srtuctures the moment of inertia is varied according to the maximum bending moment stresses. Evidently the economic relation of the limit-design and elastic methods in the design of beams with curved haunches will not be the same as that shown by the author.

The elastic theory is advantageous in that it may readily be verified by tests, whereas the limit-design method will require greater experimental and theoretical study before conclusive results will be obtained.

L. H. Donnell,[58] Esq. (by letter).—This paper is an important contribution not only to the field of structural analysis, but to fundamental engineering philosophy.

[57] "Strength of Materials," by S. Timoshenko, Part II, 1930, p. 668.

[58] Associate Prof. of Mechanical Eng., Armour Inst. of Technology (formerly in chg. of Stress Analysis and Structural Research, Goodyear-Zeppelin Corporation), Chicago, Ill.

Every one knows, but sometimes needs to be reminded, that the real object of engineering design is not to insure that stresses remain below a certain limit, but to build the most efficient structures and machines that will perform, satisfactorily, the functions for which they are intended. The method of computing stress distributions under purely elastic conditions, and comparing these with the stresses that will cause some elastic buckling, or other type of "failure," has been, and remains, a most useful tool for this purpose, but designers have long been familiar with cases in which its strict application would be not only very difficult but also highly misleading. This paper demonstrates that in other cases where designers have considered the elastic approach the most advanced method possible, another method may be simpler and may give a more accurate measure of the capacity of structures to perform their real functions satisfactorily.

Undoubtedly, this entire subject has been studied too little, with the result that there are few who have a clear, well-thought-out understanding of it. Designers should not be afraid of such questioning and reviewing of engineering fundamentals, and surely there can be no better place for this than the national forums of the great engineering societies.

The method in question is one which all designers have long accepted in certain fields of engineering, and which in essence has been accepted in some other countries in the structural field. Professor Van den Broek has made important contributions to its development, particularly in generalizing it to include compression members of trusses and other parts subject to buckling. His most important contribution, however, is in bringing to the attention of the profession, and helping to clarify, some of the gaps and inconsistencies in engineering reasoning.

It is quite possible, of course, that he goes too far in some ways in his exposition of the method, as is natural and perhaps necessary when one is combating ingrained habits. Thus it may be, as he states, that it is excessive deformation which really marks the limit of usefulness of structures. What the designer is really interested in, however, is practical means for predicting this limit of usefulness; and it is to be noted that the author does not propose to calculate this limit (and would indeed find it very inconvenient to so calculate it) by a study of the deformations of the structure. Rather he calculates it by considering the way in which the forces distribute themselves through the structure, just as in any elastic theory.

It would seem that the author does demonstrate, beyond a doubt, the following: He shows that the forces that first produce yielding or buckling in certain parts of a structure, while they may indicate the limit of strength of these parts, do not necessarily indicate the limit of strength of the structure as a whole, when these parts are redundant. He shows that when these parts are capable of yielding sufficiently, while still maintaining more or less undiminished resistance, the limit of strength of the structure itself is not reached until all the redundant parts have reached their individual limits. He shows also that this limit of strength of the structure is easily found and in many important cases differs an important amount from the strength usually calculated by much more laborious methods. He shows, furthermore, that the deformations of the parts and of the structure as a whole remain "of the order of magnitude of elastic deformations" until the limit of strength of the structure is reached.

Two things remain which do not seem to be clearly demonstrated—namely, that such deformations of the structure as a whole may not be great enough to destroy its usefulness, and that such deformations can be borne by the parts involved while still maintaining more or less constant resistance. It is no criticism of the paper to say that these questions are not adequately covered, because obviously one paper cannot be expected to cover all sides of such a subject; but it seems evident that these questions must be studied thoroughly before the method can be acceptable for application in cases where proof loading is impossible.

For most types of structures the possibility of having permanent deformations of this order of magnitude under "once-in-a-life-time" load conditions is probably not serious, and a decision as to whether this is permissible can be given offhand. In this connection it should be noted that the large deformations of steel buildings, bridges, etc., which have sometimes been produced by hurricanes or floods, are undoubtedly produced after all redundant members have reached their limits and not before.

The question of whether individual members of structures can "give" the amounts required without weakening is more difficult and requires quantitative studies of (1) the amount of giving which would be required in different types of structures, and (2) the amount which various types of members can give without weakening. Considering the first question, it is obvious that the amount of giving required will depend very much upon the type of structure, and in many cases may be very much more than maximum elastic deformations. For example, in Fig. 43, the amount bar *a* would have to stretch plastically before bars *b* would reach their yield point would depend on the angle of bars *b*, and would be $\left(\frac{b}{a}\right)^2 - 1$ times the maximum elastic strain, if the bars are all of the same material; or, in Fig. 44, the plastic strain in the tie bar *a* must be large before the stresses in the truss reach the yield point if the dimensions *a* and *b* are small compared to *c*.

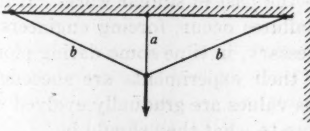

FIG. 43

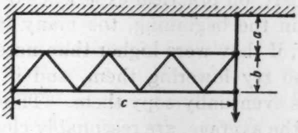

FIG. 44

Considering question (2), studies must be made of the relation between the longitudinal resistance of struts and the longitudinal deformation during local or Euler buckling, and of the relation between the bending resistance of deep beams and the bending deformation when local or lateral buckling of the compression flange occurs. There have been many theoretical and experimental studies of buckling problems in both the elastic and plastic range; but, heretofore, this particular phase of the question has not been considered important and has apparently escaped investigation.

As to members under tension, although it is true that plastic strains can be a hundred times or more as large as elastic strains in a mild steel tensile test specimen, it does not necessarily follow that this is true in structural tension members as they are commonly made, which frequently includes reductions of area and stress concentrations at the ends. To be sure, there is a powerful antidote against the obvious tendency in such cases for most of the strain to concentrate in these short, weakened sections—namely, the phenomenon of strain hardening, which stiffens up such weak points after they have yielded somewhat. However, obviously there are limits to the extent to which this favorable tendency can overcome the unfavorable, as is observed in tensile test specimens after the necking-down stage is reached. Hence some quantitative studies of this question are needed. This is especially important in view of the present tendency toward the use, for greater efficiency, of some of the higher strength materials, which almost always have lower ductility.

It should be emphasized that such studies are important not merely in order to make some new method of analysis possible, but chiefly because of the possibility which they present for making improvements in the actual ultimate strength of present types of structures through minor modification of details. Thus it might be found that certain types of tension members, although strong enough elastically, will not stand the plastic strain required to realize the full ultimate strength of the structure, and that this ultimate strength can be obtained by changing to tie-rods with enlarged ends, such as are frequently used now for economy of material and resistance to shocks. Such possibilities for increasing efficiency would not be suggested by present elastic methods of analysis.

If such studies show that no modifications are necessary in order to realize the increased strength indicated by the new method of analysis—that is, if present-type structures are really stronger than designers have been computing them to be—then the factors of safety to be used in applying the new method require discussion.

The factors of safety used in many branches of engineering are based, at least in part, on practical experience of the past in similar work. If they were too low in the beginning, too many failures occur, forcing engineers to raise them; or, if they were higher than necessary, in time some daring pioneers are certain to try lowering them, and if their experiments are successful other engineers eventually copy them. Thus values are gradually evolved which, at least on the average, are reasonably close to what they should be.

Obviously, this process is valid only when the same methods of analysis are used on the new and old designs. If engineers do not improve the type of design, and introduce a new method which gives more optimistic estimates of the strengths of structures, factors of safety based on past experience should presumably be raised enough so that structures designed by the new method will be as strong, on the average, as those designed by the old methods.

This does not at all mean that the new method would give the same results in individual cases as the old, and hence that it has no advantage other than its greater simplicity. On the contrary, a design method which gives an imperfect measure of the real useful strength of a structure, as elastic methods evidently may, can obviously result in too low a real strength in some cases and too high a real strength in others, even if it is regulated to give correct results on the average. Conversely, any method which gives a better measure of the real useful strength, as the one under discussion evidently may, will always give results closer to what they should be in individual cases; and, of course, in so far as this represents decreased uncertainty in design, the factor of safety can be reduced somewhat, counterbalancing, at least partly, the necessity for raising it.

One other point is suggested by this paper: If there is any real objection to relying on the yielding of some members of a structure under very extreme conditions, the same ultimate strengths could be obtained, without the necessity for such yielding, by the expedient of introducing initial stresses into the structure when it is built, such that under the worst conditions all redundant members would reach their ultimate loads at the same instant. Practical means for introducing such initial stresses could probably be devised if it proved worth while. Such an expedient, of course, could be fully applied only in cases where it can be assumed that loadings are predominantly in one direction.

J. A. Van den Broek,[59] M. Am. Soc. C. E. (by letter).—It is gratifying indeed to note the large number of men who, by their generous discussions, have manifested their interest in the "Theory of Limit Design." As was to be expected, the views expressed reflected unfavorable as well as favorable opinions. The unfavorable opinions are the more valuable since they are likely to lead to the greatest clarification of the subject. Of these unfavorable opinions, some are the result of misunderstanding, and others of sincere disagreement. First, an attempt will be made to clear up possible misunderstandings, after which the disagreements will be discussed.

Mr. Sourochnikoff states: "Of course, if a few extreme fibers are broken at the supports, it does not mean that the entire beam will collapse." The theory of limit design does not envisage the breaking of any fibers anywhere at any time. In the realm of structural engineering, failure is the result of excessive deformations, and rupture is practically non-existent. Where non-ductile materials are used, the principles of limit design are non-operative.

Professor Fabian devotes his major attention to the opening sentence of the "Introduction"—namely, the statement that, "Traditionally all theory pertaining to the strength of materials and to structural design is based on two major assumptions: (1) That the material is elastic; and (2) that the principle of superposition applies." The theory of limit design breaks completely with these traditional assumptions. It would seem evident, from what has gone before, that as soon as the elastic limit at any point is exceeded the principle of superposition is violated. Professor Fabian, furthermore, claims that, "Where the conditions are such that the law of superposition cannot be applied, the distribution of loads to various members cannot be made on the basis of simple statical conditions—namely, the force diagram—but it must be made on the basis of Maxwell's equations—that is, by the 'influence-line' method." No doubt it is agreed that Maxwell's equations are strictly within the limits of the theory of elasticity and are themselves predicated on the assumptions of elasticity and superposition. It is not clear, then, how they can be suggested as a tool in a field where the principle of superposition is non-operative and where the stresses exceed the elastic limit.

---

[59] Prof. of Eng. Mechanics, Univ. of Michigan, Ann Arbor, Mich.

The principle of superposition, in the theory of elasticity, is generally assumed, except in case of buckling. It is practically never rigorously satisfied. The question as to whether or not the violation of the principle invalidates the theory built on it is one of degree. It has nothing whatever to do with the theory of equilibrium (statics), which is always true.

In the example of the steel tower (Fig. 15), the force diagrams were drawn on the assumption that the geometric proportions of the structure remained substantially unaltered. In this the practice usually followed is applied. It is justified on the basis of dictum (3), which states that deformations are of the order of magnitude of elastic deformations (that is, of secondary order of magnitude), under all loads up to the limit loads, but cease to be so when the limit load is exceeded.

Mr. Floris regrets the fact that only the fixed-end beam was analyzed; and, quite properly, Mr. Meursinge and Mr. Winter emphasize the fact that the capacity resisting moment of a beam is reached when the stress distribution is rectangular rather than triangular (Fig. 24(*c*) rather than Fig. 24(*a*)). Mr. Winter, furthermore, insists that deformation analysis on the basis of theory of limit design is essential, whereas Professors Wise and Niles deny that the strength criterion in structural design is deformation rather than stress.

The writer has the impression that most of the discussers had some familiarity with theories allied to the theory of limit design, if not with the latter theory itself. His paper, however, was directed primarily to the reader with little or no familiarity with the principles of limit design. For that reason, his main purpose was to present the major idea involved with the least possible mathematical or other complexities. A fixed-end beam is a theoretical abstraction rather than a reality. It was chosen to serve as an example simply because all its properties are thoroughly well known. For the same reason, the capacity moment was assumed to be the one obtained from the familiar formula, $M = \frac{S\,I}{c}$, rather than the more logical one obtained by Equation (2), which is strictly applicable only in cases of beams of symmetrical cross-section. In the case of a beam of irregular cross-section, the neutral axis shifts as soon as the elastic limit is exceeded, and Equation (2) should be written:

$$M = S_1 (\bar{y}_1 A_1 + \bar{y}_2 A_2) \ldots\ldots\ldots\ldots\ldots\ldots (2a)$$

in which $A_1 = A_2$ (see Fig. 45). It was the desire to postpone considerations of detail such as these which lead to the assumption that the capacity-bending moment might be expressed by Equation (2). The writer stands corrected. He realizes that this is a consideration of insufficient merit and recommends that capacity moments be computed by Equation (2), or, in the case of beams with unsymmetrical cross-section, by Equation (2*a*).

As to deformations of beams subject to ductile yielding, Mr. Winter supplies some theory and certain very interesting test results. A very close agreement between theoretical and test results involving the ductile behavior of beams may be observed in Fig. 46.[60] If the deflection under a limit load (when the stress distribution resembles that shown in Fig. 24(*c*)) is compared with the deflection obtained when the beam behaves completely elastically under the same load, the ratios of these deformations are found to be: For the rectangular beam (Fig. 46(*a*)), 24/16 = 1.50; for the circular beam (Fig. 46(*b*)), 23/17 = 1.35; and for the wide-flange beam (Fig. 46(*c*)), 38/31 = 1.25. This evidence serves as proof of the claim that the deformations are of the order of magnitude of elastic deformations until the last redundant (the fibers at the neutral axis) members have reached their elastic limit.

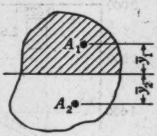

FIG. 45

Professor Wise is the only reviewer who questions the validity of the three dicta under the heading "Theory." It is conceded that without these dicta the entire theory of limit design collapses. As to the first dictum, Professor Wise calls it vague. The writer merely wanted to emphasize what he regarded as a well-known special aspect of engineering structures. The third dictum Professor Wise dismisses with a single word "incorrect." On the contrary, the writer regrets that he could not emphasize it more strongly by means of italics or capital letters, as he regards it as the very cornerstone of the theory of limit design. To test dictum (3) by Professor Wise's definition of statically indeterminate structures: He states, "The essential characteristic of a statically indeterminate structure is that it has redundant members, reactions, or restraints in excess of the number just sufficient to maintain static equilibrium." Suppose, then, that such superfluous redundant members are all stressed beyond the elastic limit. By Professor Wise's definition, sufficient members are left to form an elastic system in equilibrium. This system, as stated in the "Synopsis," behaves elastically. Hence the statement in dictum (3) that one member in the primary system (that is, one member in addition to the redundant members) must exceed the elastic limit, or buckling strength, before deformation in excess of elastic deformation will take place. It would involve extra diagrams to prove the point mathematically, but the writer suggests that the reader take any redundant structure, beam or truss, or a combination of both, and proceed to find the displacement at some point. He will then probably apply an auxiliary load at this point in the direction of the desired displacement and compute the resulting auxiliary forces in the structure. When he does so, however, he will, no doubt, in perfect conformity with the rules of the theory of elasticity, remove as many reactions, restraints, or members (in other words, redundants) as is consistent with stability. In his computations for the desired displacement, the redundants do not appear, since the forces therein, induced by the auxiliary load, are all zero. The displacement of a point in a redundant structure thus appears as the displacement of a point in a statically determinate elastic system. Hence, so long as the primary system is intact, deformations are of the order of magnitude of elastic deformations, which is all that dictum (3) states.

---

[60] "Deformations of Beams Involving Ductile Behavior," by E. O. Scott; thesis presented to the University of Michigan in 1939 in partial fulfillment of the requirements for the degree of Master of Science in Engineering.

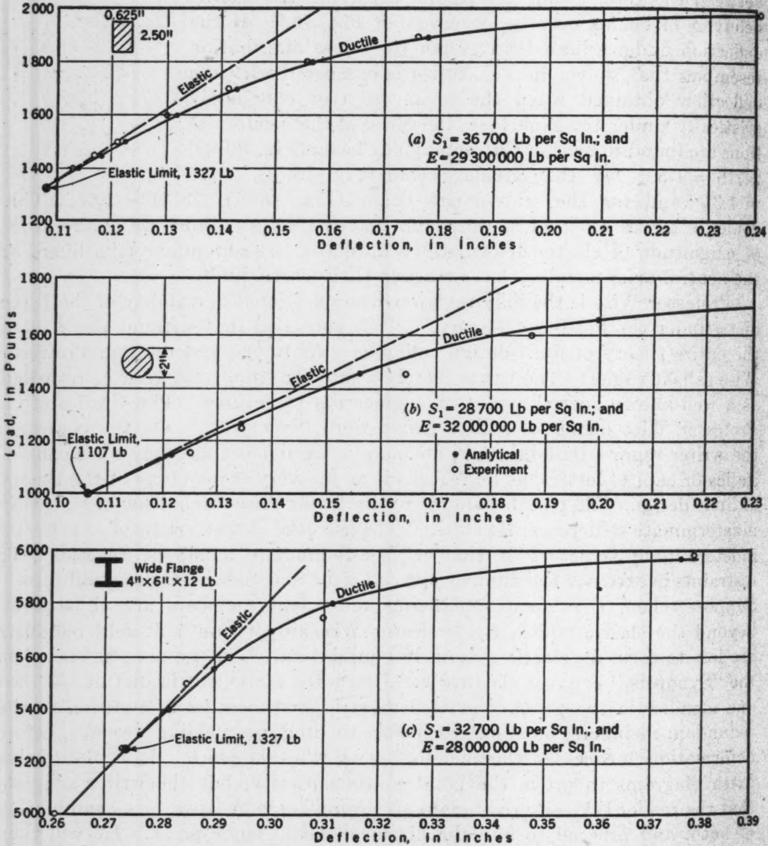

FIG. 46.—COMPARISON BETWEEN THEORETICAL AND TEST RESULTS INVOLVING THE DUCTILE BEHAVIOR OF BEAMS

There are shelves full of treatises on the theory of elasticity. The striking revelation to the practicing engineer is that the elastic deformations of a structure, in themselves, are only rarely of interest, and then generally only of secondary interest. In structural engineering the theory of elasticity is a supplementary theory. It serves the purpose (area moments, slope deflection, conjugate beams, least work, elastic energy, etc.) of writing independent equations to supplement those obtained from statics. Ask any engineer the probable stress in a modern railroad bridge, and he will give an immediate and correct answer. Ask him the probable deflection of the same bridge under load, and he is likely to want paper, pencil, dimensions, etc. The point is that, for structures of normal proportions, deflections are safe, so long as they are of the order of magnitude of elastic deflections. Failures, generally, are not the result of rupture but of excessive deformations—deformations of an order of magnitude greater than elastic deformations. In the laboratory specimens are tested and actually broken. A structural steel beam is never broken either in the laboratory or in the field. Under load it may be distorted out of shape to the point where it becomes a mass of wreckage, but in spite of the designer's emphasis on strength and on stresses, in the last instance, it is only deformation that really counts.

The writer did not state, as Professors Wise and Niles infer, that the theory of limit design is predicated upon permissible deformations, as distinct from the theory of elasticity, which is supposed to be predicated upon permissible stresses. In the "Introduction," prior to the introduction of Fig. 2, it is stated that "* * * it is proposed to continue to rely on the criterion that always was the primary one, the criterion of permissible deformations." In a statically determinate beam in a building, the designer generally is not concerned about deformations so long as the stresses remain within the elastic limit. Dictum (3) maintains that, in a redundant beam, even when the redundants have become completely ductile, the deformations are not of a magnitude that would give the structural engineer especial concern, because the primary system still remaining behaves in the manner of a statically determinate, purely elastic, beam with deformations of relatively small order of magnitude.

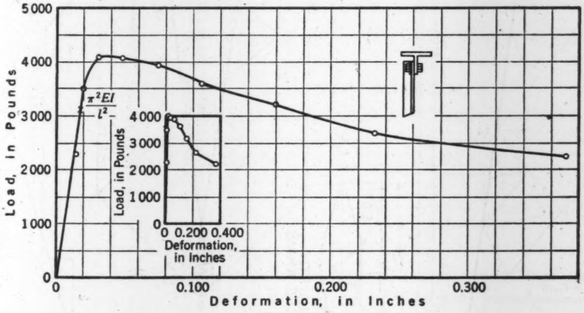

FIG. 47

Mr. Meursinge calls attention to the importance of connections. Specifications emphasize the importance of the property of ductility, but in order that this property may be made effective, the connections must be so designed that the yield point in the main part of the member is exceeded before the connection fails. In the discussion of the tower (Fig. 15) the connections were assumed to be welded in order to keep the argument simple and postpone the consideration of complexities.

Elsewhere[61] the writer has shown the results of a series of tests on 1¾-in. by 1¾-in. by ⅛-in. angle irons such as are commonly used as diagonal bracing in transmission towers (see Fig. 15). Bolt connection of an angle iron through one leg weakens the iron on two counts—the reduction of net area and the eccentricity of the applied load. By perforating both legs of the iron with extra holes, the strength of the iron is somewhat increased and the ductility of the member is augmented in proportion to the number of extra holes. Different types of end connections of angle irons and different degrees of perforation show marked differences in strength and even greater variations

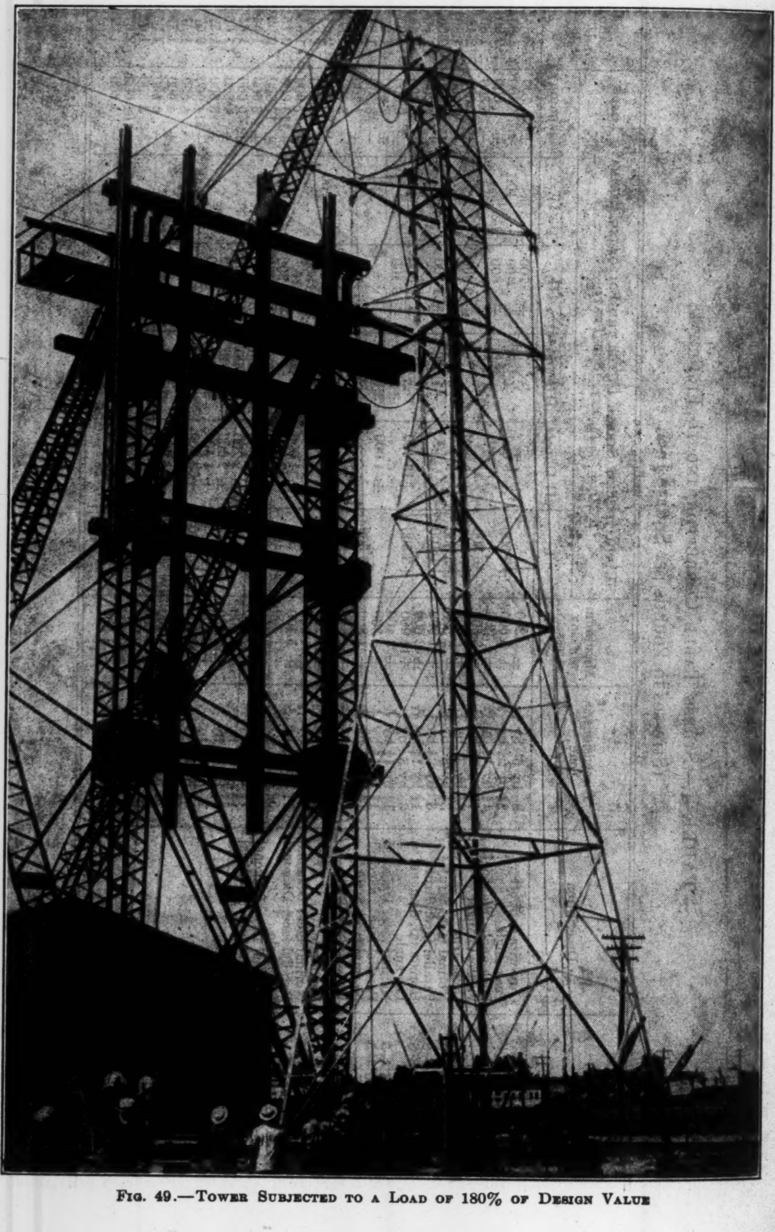

FIG. 49.—TOWER SUBJECTED TO A LOAD OF 180% OF DESIGN VALUE

in ductility. Fig. 47 shows the load-deformation relationship of a 1¾-in. by 1¾-in. by ⅛-in. angle with a slenderness ratio of 200 in compression. Figs. 48, 49, and 50 illustrate the results of a test of a full-size transmission tower, 55 ft high.

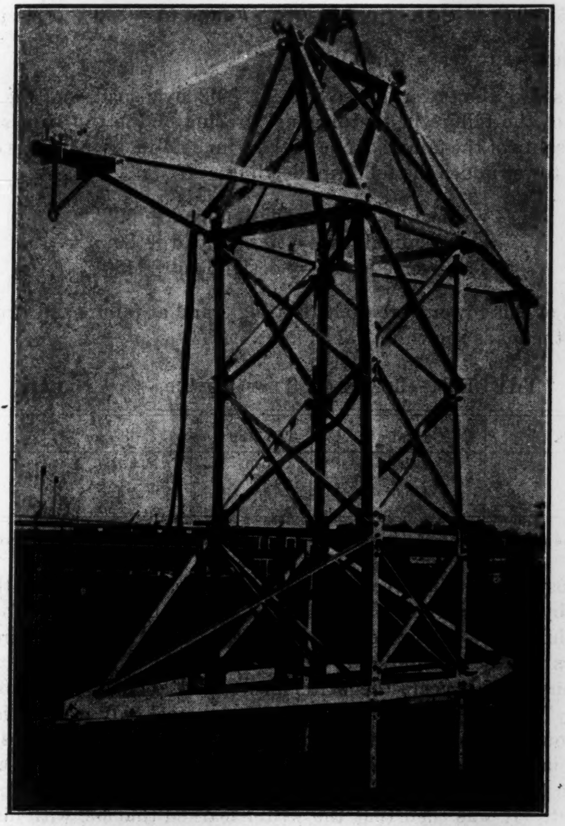

FIG. 50.—ENLARGED VIEW OF THE FAILURE (SEE FIG. 49)

Stress diagrams are shown in Fig. 48, with corresponding stresses in Table 4, the ultimate loads being identified as follows:

I. Vertically downward
  (*a*) 2 160 lb at Point A = 180% of design load
  (*b*) 3 240 lb at each of points B, C, D, E, F, and G = 180% design

II. Horizontal parallel
  (*a*) 6 120 lb at Point A = 180% of design load
  (*b*) 5 760 lb at Point C = 180% of design load

III. Horizontal normal

(*a*) 1 300 lb at Point A = 306% of design load
(*b*) 7 290 lb at Point B = 424% of design load
(*c*) 7 290 lb at Point C = 610% of design load
(*d*) 5 730 lb at each of points D, E, F, and G = 333% of design load

IV. Weight of tower = 9 600 lb

Fig. 49 shows the tower loaded with an 80% over-load, and Fig. 50 shows a close-up of the failure in the diagonal bracing of the top panels. Fig. 51 shows a close-up of the failure of one of the 4-in. by 4-in. by ⅜-in. legs of a heavy suspension tower under the following loading:

Vertical load = design load + 80%
Longitudinal load = design load + 80%
Transverse load = design load + 180%

The panels of this tower were each 10 ft high, and at failure the structure was sustaining the loads shown in Table 5.

TABLE 5.—LOADS ON TEST TOWER, AT FAILURE

Loads	Guy wire	Top arm	Mid-arm	Bottom arm
Vertical...............	1 620	3 060	4 500	4 500
Longitudinal...........	4 680	5 400	....	....
Transverse*...........	4 600	5 460	7 160	7 160

* The wind load was compensated by an addition of 750 lb to the transverse load at each of the four points.

The most serious disagreement revealed by the discussion is the opinion advanced by Messrs. Bleich, Freudenthal, Mirabelli, and Wise to the effect that the philosophy of limit design is not applicable in cases where buckling of members may be encountered.

For some twenty years the writer has talked about a theory of ductility ("plasticity" is a term applicable to structural steel only when it is red hot). In every course he gives on the theory of elastic energy the lectures are closed with a discussion of the limitations of the theory of elasticity. On one such occasion, in 1924, at the termination of a course in Detroit, Mich., Mr. Goodrich was present. It was then that the writer learned that he, with his theory of ductility, and Mr. Goodrich with his design practices, talked essentially the same language. After innumerable discussions with Mr. Goodrich, the term theory of ductility was abandoned and the term "theory of limit design" was substituted, so as to make the title applicable to trusses involving members subject to buckling. Whereas some men (Professors Mirabelli and Wise) merely question the application of the theory of limit design in cases where buckling may occur, others (Messrs. Bleich and Freudenthal) conclude definitely that such application should not be permitted.

The writer's reply is two-fold. The first is that Fig. 47 shows that although the load-deformation relationship for a member in compression is not the

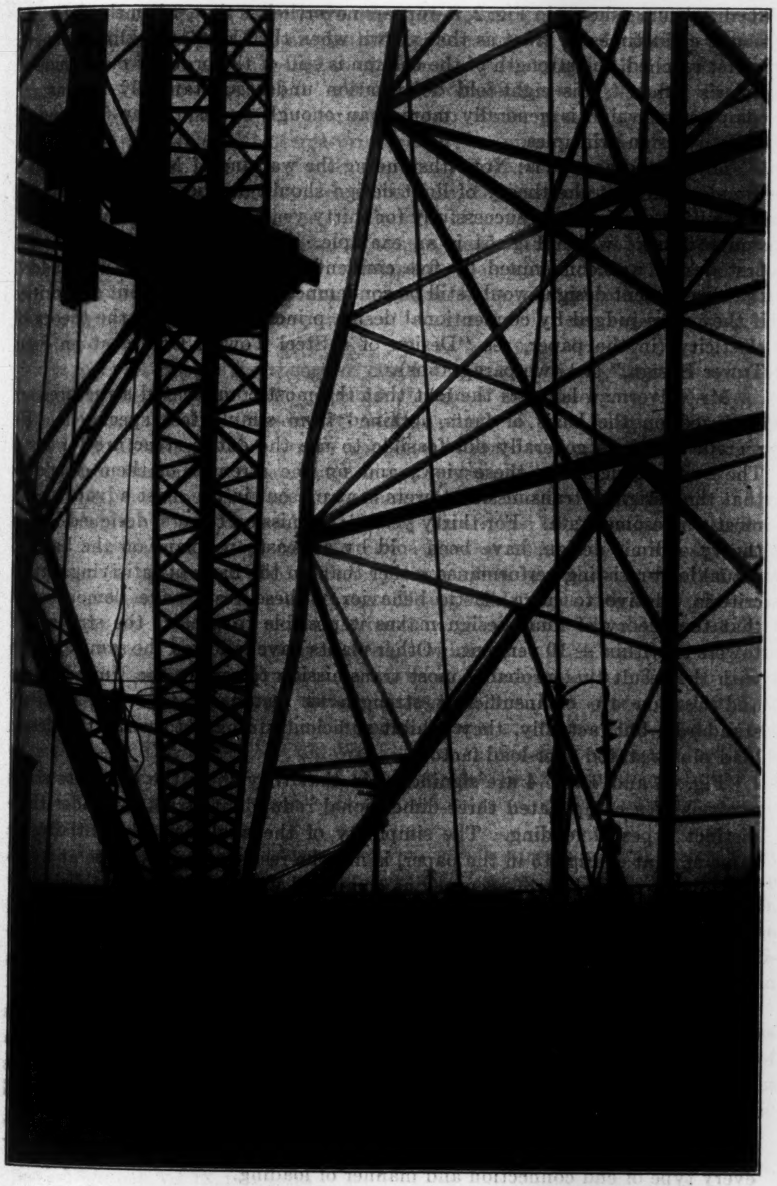

FIG. 51.—FAILURE OF ONE OF THE LEGS OF A HEAVY SUSPENSION TOWER

idealized curve shown in Fig. 2, it appears nevertheless that, when the deformation is eight times as great as that shown when the Euler's buckling strength is first reached, the strength of the column is still of the order of magnitude of Euler's value. This eight-fold deformation under substantially a constant compressive value is generally more than enough to insure the functioning of limit-design principles.

The second answer is: Notwithstanding the warning of Messrs. Bleich and Freudenthal that the theory of limit design should not be applied to trusses, it has been applied very successfully for thirty years to the design of transmission towers of which Fig. 51 is an example. Mr. Goodrich states that his first design was condemned by five eminent authorities. It may be added that his present designs would still be condemned by other eminent authorities if they were judged by conventional design principles based on the theory of elasticity (in the paper, see "Design of a Steel Tower: Comment on Steel Tower Design," last two paragraphs).

Mr. Silverman laments the fact that the most complicated structures are analyzed on the basis of facts obtained from simple test specimens. He regrets that it is generally not feasible to use the entire structure for tests. The writer concurs in these views and on the strength of them concludes that the design of transmission towers is at present in the most advanced and most wholesome state. For thirty years transmission towers, designed by the theory of limit design, have been sold by at least one plant on the basis of actual load-resisting performance rather than on the basis of satisfying certain criteria relative to mere elastic behavior. These tests have demonstrated that the theory of limit design makes it possible to predict the strength of towers to within ± 10 per cent. Other plants have followed the same example with the result that probably most transmission towers in the United States and Canada are of insufficient strength as tested by theory-of-elasticity standards; but, actually, they exhibit sufficient strength to carry the design load plus a stated over-load factor.

Fig. 48 and Table 4 are significant in that they show the complete stress analysis of a complicated three-dimensional redundant structure under three distinct types of loading. The simplicity of the analysis, substantially the same as that of Fig. 15 in the paper, is not the result of compromise and does not involve a sacrifice of accuracy as compared with standards established by stress analysis based on Hooke's law. On the contrary, it has a two-fold merit: First, that of great simplicity; and second, the merit of very satisfactory agreement with observed facts, as established by innumerable tests. It is conceded that the load-deformation relationship of columns beyond the buckling load is an involved one, affected as it is by end-connection, slenderness ratio, and eccentricity of applied load. In spite of innumerable tests on columns, which have been recorded, this particular relationship appears practically never to have been measured. Before limit-design principles will be applied with confidence to any type of truss, other than transmission towers, such data should be obtained for every type of compression member under every type of end connection and manner of loading.

Mr. Meursinge, very aptly, quotes Professor Kist to the effect that Hooke's law and theory of ductility are both "simplifications of a very intricate reality * * *. Both may be compared to cartoons, because they both 'express reality in a very primitive manner.' " The writer's only hope is that the theory of limit design is not too much of a caricature. Quite properly, Professor Niles warns against using limit-design principles where materials are involved which do not behave in agreement with Fig. 2. Wood, concrete, and earth do not obey Hooke's law rigorously. Nevertheless, the designer commonly applies strength-of-materials formulas to them, which are based on Hooke's law. This procedure is fully justified, of course, when a proper factor of safety is used. Similarly, limit-design principles may be applied, with reservations, to structures built of materials that are imperfectly ductile. The reservations naturally become prohibitive when the material is completely lacking in ductile properties.

It was not due to the theory of elasticity, but rather to the good sense of structural engineers (possibly without the aid of any theory to which a label could be attached, but nevertheless the result of sound logic and correct observation) that such materials, completely devoid of ductile properties, were never used for structures such as bridges, towers, buildings, or airplanes.

Mr. Silverman refers to Timoshenko,[21] even as does Mr. Eremin. Mr. Silverman, however, correctly attributes the original contribution not to Professor Timoshenko but to Mr. Hencky. Furthermore, Mr. Silverman points out that the agreement of Mr. Hencky's contribution with the theory of limit design is incidental, which is very gratifying. Mr. Hencky's contribution is offered as an attempt to explain what Mr. Silverman calls the Bauschinger effect—namely, that the effect of cold working on steel in tension is to raise the elastic limit in tension and to lower it in compression. This so-called Bauschinger effect has two serious flaws. In the first place, Bauschinger never made this claim; and in the second place, the claim when made is not true. (See "The Effect of Cold Working on Elastic Properties of Steel,"[62] in which an entire chapter—entitled "Cold Stretching Steel Does not Lower Its Elastic Limit in Compression"—is devoted to refuting this commonly found erroneous statement.)

Professor Donnell's discussion is very much appreciated as being most constructive. He "hits the nail on the head" when he states: "There have been many theoretical and experimental studies of buckling problems in both the elastic and plastic range; but, heretofore, this particular phase of the question [the relation between longitudinal resistance of struts and the longitudinal deformation during buckling] has not been considered important and has apparently escaped investigation."

The theory of elasticity has not only dominated methods of design but has controlled research as well. To return to the original thesis: If the theory of elasticity is so excellent, why not specify purely elastic material; and, *vice versa*, if the engineer realizes that he cannot possibly build with purely elastic material, then why not include the property of ductility in design theory?

---

[62] "The Effect of Cold Working on the Elastic Properties of Steel," Carnegie Scholarship *Memoirs*, Iron and Steel Inst., Vol. IX, 1918, p. 138.

The writer is unable to accept two alleged statements of fact made by Mr. Freudenthal. In Section (2) of his discussion Mr. Freudenthal states that "Instantaneously applied loads cause the upper yield point to drop." In the writer's opinion the reverse is the fact. In structural steel, the corner at Point *B* as shown in Fig. 2 is the sharpest when loads are applied slowly. In Section (3) Mr. Freudenthal states: "The occurrence of pulsating and reversed stresses will always demand the design of bridges on the basis of the endurance limit of the material." Reversal of stresses in bridges is so rare as to constitute the exception rather than the rule. Furthermore, although capacity loads for certain details[63] (for example, stringer connections to floor beams) may occur each time a heavy locomotive passes over the bridge, capacity loads for the entire truss may not occur oftener than once or twice in the life of the bridge. Therefore, although fatigue must be considered in connection with bridge design, it is of secondary and not of primary importance.

The writer desires to express his indebtedness to The Canadian Bridge Company, Ltd., for permission to reproduce illustrations, to Mr. Goodrich for his unfailing interest, and to the Horace H. Rackham School of Graduate Studies of the University of Michigan for aid received in providing assistance and in furthering tests herein recorded.

PROPOSED IMPROVEMENTS FOR LAND SURVEYS AND TITLE TRANSFERS

BY PHILIP KISSAM,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. GEORGE D. WHITMORE, AND PHILIP KISSAM.

SYNOPSIS

The transfer of real estate in the United States is surrounded by difficulties out of all proportion to the values involved. This is particularly obvious when a comparison is made with the transfer of any other form of wealth. The unnecessary costs and delays, the investigations, surveys, and uncertainties of boundary location, the prolonged procedure used in proving title—all tend to reduce the negotiability of real property and to damage its value.

Surveying equipment, skill, and procedure have been developed which give results far beyond the accuracy required to eliminate boundary difficulties, and methods of recording title have already been successfully employed which eliminate delays in title search. It appears to the writer that the time has come for surveyors and title examiner to combine in a joint effort to find ways and means for employing these excellent tools already at hand.

The uncertainties of boundary location are caused basically by: (*a*) A lack of permanent, recognized, and correlated monuments from which surveys may originate; (*b*) increasing land values with no provision for more accurate surveys; (*c*) faulty descriptions (not erroneous); (*d*) blunders in description and surveys; and (*e*) the rules of adverse possession in force where accurate surveys and proper title records eliminate their usefulness.

The difficulties of title search are caused by: (*a*) The many and ever-increasing sources of information and records that must be studied; and (*b*) recurrent study of the same information and records.

To eliminate these difficulties the writer recommends:

(1) The establishment of State Systems of plane co-ordinates;

(2) A public officer to aid in, and permanently record, the determination of boundary lines for properties above an assessed unit value;

NOTE.—Published in April, 1939, *Proceedings*.

[1] Associate Prof. of Civ. Eng., Princeton Univ., Princeton, N. J.

(3) The assignment of certain members of the judiciary to a Land Court where title can be confirmed at the cost of only a small fee for legal service; and

(4) Simplification of title records by making a court decree final, with only a limited time for appeal, and by requiring all liens to be recorded with the evidence of title.

Introduction

One of the primary elements of civilization is the dedication of land areas to definite purposes. Devices for maintaining life, reducing labor, regulating men's relationships, providing enjoyment, or protecting spiritual values cannot be developed or used without the assignment of land. When the purpose of the dedication becomes clouded, or when the delineation of areas becomes vague, such confusion arises that progress is threatened. These truths are so fundamental that they are accepted without question. They are so well recognized that the first step upon the occupation of new territory is the assignment or division of land. They are so immutably fixed in men's minds that wholesale disregard of them is never contemplated.

Wherever the principle of private ownership obtains, possession of land carries with it the right to direct the use of the land under certain restrictions. It is therefore important, if progress is to be expected, that ownership and the limits of ownership shall be clearly defined.

It follows that land ownership must be a matter of public record, and that therefore it must be a function of government to maintain these public records. Not only must the records show who are the owners of the various land parcels and the conditions of ownership, but they must also clearly define the boundaries of the holdings. If land is to have its greatest value, it must be readily negotiable. Therefore, the public records must be quickly available and of unimpeachable accuracy. Each State must insure through legislative enactment that such conditions shall obtain, if confusion and serious economic loss are to be avoided.

How far has the United States progressed toward this goal? Unfortunately, in all the States, records of title and of liens affecting title are not only difficult of access but often require an expert to find them. They are frequently inconsistent with each other so that unless the title examiner's opinion is accepted, a court decree is necessary to bring them into agreement temporarily.

Are the conditions of the records of location any better? On the contrary, they are frequently worse. Recognition of position is usually based on hearsay, while size and shape may rest on the integrated opinion of many individuals. Under these conditions it can hardly be supposed that the parcels presumably owned will fit the existing ground, or that the location of a single parcel can be independently determined. Every land surveyor realizes this. Furthermore, the systems of recording are archaic, inadequate, and impractical. Obviously, therefore, the time has come for a change.

THE JOINT COMMITTEE

As civil engineers are continuously engaged in the design of structures and projects necessitating the acquirement and use of land, and as land surveying is also one of their functions, they should take the lead in initiating steps to bring about betterments. Furthermore, the locating of property is so intimately connected with its title that changes in procedure in regard to location must be accompanied by changes of procedure with regard to title. At the request of the Society, acting through its Surveying and Mapping Division, a Joint Committee has been formed with the American Bar Association, represented by the Real Property Division of its Section of Real Property, Probate and Trust Law. Presumably it will require some time for this Committee to formulate recommendations and make a final report.[2] Certain ideas brought out in Committee discussion are here described, although none of the statements in this paper represent action of the Committee, nor will they necessarily be included in the Committee's report.

BOUNDARY LOCATION

Whatever function a land surveyor is called upon to perform, he must first locate the boundaries of a parcel of land, even if a subdivision is required. If he can locate one corner and the direction of one line extending from that corner, a large portion of his difficulties are overcome. To aid him, the description of the parcel recorded in the deed probably is available. If this description is not independent, but is based on some other division of the land, he must resort to the earlier description. Sooner or later he must find mention of a point of beginning and some description of it. If this point is a natural or artificial monument, he is fortunate, provided check measurements made from other points he believes to be correct prove that the monument is in its original position.

Frequently the point of beginning is not marked, but is described as being so many feet along the center line or boundary of a public highway from some other public line. It is unusual if either of these lines can be found. Moreover, the surveyor never is sure that the present locations of these public lines, or his best judgment of where they should be located, will agree with the location assumed by the person who first described the point of beginning. In other words, more evidence must be brought to bear besides that found in the deed itself; and so many elements must be considered in each case that more judgment than skill is often required to establish even the initial point and direction.

To overcome this difficulty, recognized official survey positions must be provided by which property can be described and relocated. Systems of official monuments must be established and inter-connected by accurate surveys so that each monument is witnessed by all the others. When five or six monuments constitute the entire system, a balanced traverse loop will tie them together satisfactorily, and a plat showing the various adjusted traverse distances and angles will serve as a record of their positions. Any municipality can safeguard the property in an important section of town by establishing a small system of this kind, recording the plat at the registry office, and maintaining the integrity of the monuments by re-surveys or check witness measurements at intervals. A purchaser of real estate in this area should be advised by his title examiner and his surveyor to demand a description in his deed based on these monuments.

---

[2] "Land Surveys and Titles," First Progress Report of the Joint Committee of the Real Property Division, American Bar Association, and the Surveying and Mapping Division, American Society of Civil Engineers, *Proceedings*, Am. Soc. C. E., November, 1938, pp. 1879–1884.

It is better to substitute for the adjusted traverse data a rectangular co-ordinate system. The land surveyor need then only state the co-ordinates of each point mentioned in the description and name the co-ordinate system used. If possible, the co-ordinates of street intersections should be given on the plat. The title examiner will then have more information for tracing the title, and the public property will be better protected.

But when more than one co-ordinate system is established, it is inevitable that the systems will be extended until they meet, and then confusion will result. It is therefore desirable to have a few large systems rather than many small ones.

STATE PLANE CO-ORDINATE SYSTEMS

The United States Coast and Geodetic Survey has established a system of plane rectangular co-ordinates for every State in the Union.[3] Each system is composed of one or more definite mathematical projections which are so well designed that they can be 150 miles wide and of any length desired without introducing material divergences, due to the earth's curvature, between actual measured distances or angles and those given by the co-ordinate positions. The usual maximum divergence is one part in 10 000, and for the greater part of each system the divergence is far less. The adaptation of these projections to the various States is chiefly the work of O. S. Adams of the Coast and Geodetic Survey, and the transverse Mercator projection was especially developed by him for this purpose.

HORIZONTAL CONTROL SURVEYS TO SUPPLEMENT THE FUNDAMENTAL NET

To use these systems it is necessary only to connect a survey with the Fundamental Triangulation Net of the United States. Wherever Coast and Geodetic Survey first- or second-order triangulation exists, this can be done immediately. The geographic positions of the triangulation stations can be reduced to plane co-ordinates by a comparatively simple computation. For many triangulation stations the Coast and Geodetic Survey has already made these computations. Of course it is better to amplify the triangulation net by horizontal control surveys supplemental to the Fundamental Net. This can be done by second-order traverse and, if plane co-ordinates are used, all reductions can be made by the usual plane surveying methods. Latitudes and departures are determined and the adjustment is made proportional to the lengths of the courses.

---

[3] See "Development of State Grid Systems," by O. S. Adams, *Civil Engineering*, January, 1937, pp. 33–37.

When control of this kind is developed, a sufficient number of control points presumably will be established in each town or locality so that surveys can be extended throughout the streets by local authorities.

ENABLING ACTS

Each State legislature should pass an enabling act, naming and describing the State system, so that State co-ordinates can be used in descriptions, and can be identified simply by naming the system. In New Jersey, Pennsylvania, and New York this has already been accomplished. Also, as soon as possible, in each State a survey bureau should be established to extend the control or supervise the establishment of control in various localities. Such bureaus should be the repositories of control survey data, should disseminate these data to the public, and should maintain the monuments. Pennsylvania has already established such a bureau by law; and in certain other States, control survey organizations act in this capacity.

With a State co-ordinate system, or other legally recorded co-ordinate system, the land surveyor has at his disposal a method of establishing a point of beginning and an initial direction which can always be precisely re-established. Such a system should not be confused with the Public Land System, for which the monuments (except in Alaska) are not inter-connected by precise surveys, and therefore are not susceptible of accurate replacement.

The method of describing property under the Public Land System has many advantages, particularly in tracing title. From the description alone previous title holders can be identified immediately, a procedure requiring infinite time and pains for rural districts in the East. The description gives the approximate location of the property, the description of the adjoining tracts, the approximate area of the parcel and a means of indexing the deeds by locality. However, it is impossible to define, in the description, the precise location of the property without resort to the marks originally established on the ground. They bear no mathematical relation to each other except in the roughest sense. When lost they can seldom be replaced in their original position and without the introduction of another survey it is impossible to determine rectangular co-ordinates for them. The State Plane Co-ordinate Systems provide all the advantages of the Public Land System and in addition provide a means of defining, precisely, the location of the land on the ground.

DESCRIPTIONS INCONSISTENT WITH EACH OTHER

There is a further difficulty, however. Should the surveyor try to mark a land parcel according to its description, it is very likely that he will encroach upon or fail to connect with abutting property. The shapes of the parcels described in the deeds seldom fit together to form the original tract from which they were separated. The blocks are not of the recorded length; the same line will have different lengths in adjacent lots; old boundary lines long established at inconsistent positions have become fixed by the rules of adverse possession, and the angles in possession are seldom as found in the deeds. Moreover, the adjacent properties are usually indifferently marked on the ground so that the surveyor is completely in the dark if he attempts to disregard these inconsistent deeds.

There are five causes for these inconsistencies: (1) Lack of marked, recognized, and recorded positions, as already discussed; (2) variation in land values; (3) faulty descriptions (not erroneous); (4) blunders in descriptions and surveys; and (5) adverse possession (corollary of inconsistencies).

Variation in land value is a very natural reason for inconsistency. Survey accuracy is directly proportional to survey costs. Therefore, farm lands should not be surveyed with the same accuracy as business lots. Thus, precise measurements made in business areas usually disclose discrepancies in original surveys.

Although there is much diverse opinion relative to what constitutes a proper description, from the surveyor's point of view it should completely describe the size, shape, location, and orientation of the actual holdings. As such determination is next to impossible, many palliatives have been used, none of which has been satisfactory. Little reform can be expected until the causes of inconsistencies are removed.

Further, there exists a definite disagreement of purpose in descriptions. The title examiner needs a description which may be followed back accurately through previous transfers. The surveyor needs a description that can be used to mark accurately the present holding. The repetition of an inaccurate description copied from deed to deed is a boon to the title examiner, but is fraught with difficulties for the surveyor. A new and accurate description presents difficulties for the examiner. Mention of the abutters is good policy and aids both the examiner and surveyor, but without dimensions it is useful only to the examiner. It seems evident, therefore, that the solution of these difficulties must satisfy the needs of both examiner and surveyor.

How are these difficulties handled at present? If the surveyor is to make a proper location he must make a complete survey in the field of all the existing landmarks in the original tract or city block. He must abstract all the deeds for this area and, using his best judgment, work out a consistent solution which will satisfy the deeds, the physical location, and the requirements of geometry. If no objections are raised, his location usually stands, and, if court action ensues, he is well prepared for defense.

In such a procedure, however, the survey work is costly indeed. It cannot all be charged against the one parcel to be located. In substance the surveyor has worked out the solution for all the lots in the tract. Thus he has been obliged to invest a considerable fund in the area and he must protect his investment. He is forced to use secret marks so that he alone can profit by additional surveys in the same area, and he must maintain a complete office record of his solution and of the marks which show it on the ground. Actually, he has created a public benefit by his work, but this is available only when he is employed.

As long as surveys are made according to his solution and based on his system of marks, no difficulties will arise; but this is obviously impossible. The general public is unaware of the importance of his marks and records and will employ any surveyor offering a lower bid. The public streets and other properties will not necessarily be made to agree with his solution and there is every likelihood that his office will not continue long enough to make his solution fully effective.

This leads to the second step in the reconstruction of land surveying methods. A public office must be maintained under the direction of an able land surveyor whose duty it is to see that when a deed is recorded the description is based on an accurate survey; that an adequate system of enduring monuments exists to mark the property permanently; and, finally, that the location is consistent with the surrounding holdings. This may appear to be an impossibility, but such is not the case. In Massachusetts, C. B. Humphrey, Land Court Engineer, performs all of these functions for land to be registered in the State.[4] After a land court decree, an official plat is drawn, so complete that even many years thereafter a surveyor entirely unacquainted with the area could mark the property.

The establishment of a system of this kind would be an immediate and important improvement. It would necessitate the appointment of a State surveyor-general with a deputy at each registry office. An unnecessary hardship would be created if it were made obligatory to bring all land under the system at once, as a certain fee would be required to cover the costs to the State. It would be better to require that, in order to record a deed to property assessed at perhaps $75 per front foot, there must be attached, in lieu of a description, a plat of the property issued by the deputy surveyor-general. This would stabilize property lines where the need was greatest, and require by law only an expenditure for surveys which should be made in any event under present conditions. Under this arrangement, the surveys would be made by private surveyors to whom the records of the deputy surveyor-general would be available. Their work would be checked, as is done in Massachusetts, and any control surveys necessary for solution where inconsistencies developed would be made by the surveyor-general's staff. Should suit be brought threatening any location prescribed, the surveyor-general would be required to defend the owner. As his records would probably be very complete, unless a blunder had been made, his evidence should be sufficient to bring a favorable decision.

ADVERSE POSSESSION

With State co-ordinate systems, or even local co-ordinate systems, officially marked, recorded, and maintained by a proper bureau, the first difficulty would be eliminated, namely, indefinite initial position and direction. With an able surveyor-general there would be a gradual elimination of the inconsistencies due to: (1) Previous indefinite points of beginning; (2) old surveys made when the land had less value; (3) faulty descriptions; and (4) blunders in surveys and descriptions.

Adverse possession still remains, however, as a factor with disruptive possibilities. It is based on a principle of major importance. Possession is said to be nine-tenths of the law; and it is very proper that it should be so considered, as its effect is to stabilize ownership. It protects the owner against the innumerable possibilities of loss of title to all or part of his land which may arise under the present system; but it is an admission of the failure of the system. If a proper system is established, adverse possession becomes a threat rather than a stabilizing influence. It can be eliminated only when a system is established which is so nearly perfect that there can be no fear of unknown claims arising. Such a system must require very careful and complete study of conditions affecting the title, together with the citation and hearing of all persons interested. A court decree would also be required, which, when issued, would constitute a barrier to any inquiry into title prior to that time; but the effect of the decree would not be lasting and a new or supplemental decree would be required whenever the property changed hands. To overcome this defect and reduce the difficulties connected with title search, the Torrens System was devised, and in some form has been adopted in a number of States.

---

[4] "State-Wide Surveying Practice in Massachusetts: A Symposium," by Elmer C. Houdlette and Clarence B. Humphrey, *Proceedings*, Am. Soc. C. E., November, 1938, pp. 1847–1878.

THE TORRENS SYSTEM

Briefly, the Torrens System provides the means of obtaining a certificate of ownership when a petition is presented in court. The original certificate is kept at the office of registry, and a duplicate is given to the owner. This certificate is complete evidence of title. On it must appear a record of all liens against the property, except Federal liens and recent tax liens. References are given to the proper documents. Liens not appearing are invalid. When the property changes hands, a new certificate is issued upon presentation of the owner's certificate and the filing of the deed. In order to procure the first certificate, the owner must apply to the court. The court appoints an examiner who makes a thorough examination. Upon receiving the examiner's report, all persons possibly interested are cited, and after a short interval the court holds a hearing and issues a decree. The recorder immediately issues the certificate according to the decree.

The weakness of the system is twofold. Usually no attempt is made to find the location of the property, nor to register its location. Also the petitioner bears the cost of registration, which is of no more advantage at the time than an ordinary court decree. Although forms of the Torrens System have been adopted in many States, the extent of their use is negligible in spite of the fact that all of the serious difficulties of search are eliminated, as is also the fear of unknown claims arising. Most of the Torrens Acts also establish an assurance fund to protect the petitioner if loss is incurred. It is questionable whether this is a proper governmental function or should not be left to private title companies.

THE TITLE COMPANIES

A properly operated title company offers considerably more security than the Torrens System. It brings about, unofficially, the elimination of location inconsistencies and arduous title search. Thus the owner is usually protected against the threat of subsequent redetermination of his boundaries as well as against any unknown claims arising. Such companies should maintain complete survey records of all solutions, as well as complete abstracts of title for the tracts of land where they operate, although maintenance of the survey records is sometimes left to a practising surveyor. With these records, location and title search are quickly and accurately performed.

There is no assurance, however, that any company will be the sole repository of all the survey records for any tract. Inconsistencies may arise between the solutions of two companies. Also, the title company system provides no means of clearing a clouded title, and frequently where location solutions, or title difficulties, require a court decree, the costs of both the insurance and the decree prohibit clearing the title.

In Massachusetts a splendid system has been in operation since 1898, with a special court, called the Land Court.[4] Under this plan are included all the elements necessary to the successful administration of land ownership.

CONCLUSION

It appears that certain elements are necessary to improve land surveys and title transfers. These elements can be obtained gradually by progressive steps, or they can be created simultaneously:

(*a*) Of first importance are the State Systems of Plane Co-ordinates. They provide precise initial positions and directions so as to give descriptions definite meaning and property definite position. These systems require enabling laws, and the establishment of supplemental control surveys and a State survey bureau to administer them.

(*b*) Inconsistencies between deed descriptions may be eliminated by the appointment of a surveyor-general to supervise the surveys and descriptions for properties above a certain unit value, when the deeds are to be recorded. He must make solutions for these inconsistencies in each tract required, maintain public records of his solutions, and defend his solutions in court.

(*c*) A land court should be established; after proper citation of interested parties, and a review of examination of title, it will issue a decree which will include a description approved by the surveyor-general, will constitute a barrier to any prior inquiry into title, and will be filed at the office of the register of deeds for public reference.

(*d*) Finally, there is the question of simplification of current records. Whether this can best be handled by title registration, or by title companies, appears to be a question. Certainly a title company can render more varied and comprehensive service. Probably the answer lies in the ability, strength, and administration of the title companies themselves.

None of these essential elements is revolutionary or especially costly. State co-ordinates provide a basis for the accurate maps and plans so necessary for engineering progress, afford a method of compiling map data for planning in detail and over large areas, and justify their cost even when used only for control for tax maps.

A surveyor-general would perform a service which is required at present. He would function only by bringing under one head all the unco-ordinated efforts of many land surveyors privately attempting to make solutions for boundary tangles, which, to be effective, must be of public record.

The land court is only an assignment of certain of the present judiciary to a court which will handle all real estate title matters. It has been estimated that a decree to confirm title would cost the State little, or nothing, and the petitioner about $25 for legal fees.

Title companies under such a system could insure with less risk and therefore for lower fees. The difficulty of maintaining their records would be reduced to a minimum.

With these objectives as a goal and with the concentrated effort of all who understand these problems and realize their importance, the attainment of proper methods for land surveys and title transfers cannot be far in the future and the people can look forward with considerable hope that the present inadequate, archaic, costly, and wasteful methods of determining land ownership have not long to last.

DISCUSSION

George D. Whitmore,[5] M. Am. Soc. C. E. (by letter).—The author has presented the case for better land surveys and title transfers quite clearly and convincingly. The writer, a practicing land surveyor, whose area of activity extends into several States, finds little to question or dispute in Professor Kissam's summary of the situation. Changes in land-surveying and title-proving procedures must come, and are in fact already slowly beginning, along lines suggested by the author.

There seems to be no question but that surveying equipment, skill, and techniques have been developed which, if applied, would largely eliminate land-boundary difficulties. The real problem seems to be that of bringing the equipment, skill, and techniques into general use. The Joint Committee of which the author is a member may find that there is relatively little difference of opinion as to what should be done; but they may find a discouraging amount of inertia in trying to get the recommended procedures actually used. It would seem that the Committee should organize itself for a long-range program of two parts: (1) Relatively simple (and apparently well advanced) to get agreement on sound basic procedures between the legal and engineering professions; and (2) (and much more difficult) to get these procedures adopted and into general practice.

There is one matter which the author's summary does not seem to cover, and which seems to the writer to be of greatest importance in the matter of improved land surveys—that is, improvement in the accuracy of the surveys and resulting descriptions or plats. Accurate co-ordinates will permit the accurate replacement of any lost corner by means of routine surveys; but they are a result of, and not a cause of, accurate surveys. Hence, it seems to the writer that more emphasis needs to be placed on accuracy of the surveys, whether these be control surveys, boundary traverses, or traverses connecting control surveys to the boundary surveys. It is the writer's belief that 80% to 90% of the trouble which surveyors now have in trying to re-establish lost or obliterated property corners would be eliminated if the original boundary surveys and deed descriptions had been accurate and free of blunders. If, also, all the accurate surveys had been tied together and computed on a State-wide co-ordinate system, there would be practically no difficulty of any kind in re-establishing lost corners. In other words, the simple requirement that boundary surveys shall be co-ordinated through traverse connections to co-ordinated control points, although of the greatest importance, is not in itself sufficient—there must be the requirement that these surveys shall be of a certain degree of accuracy and blunder-free.

The outstanding proof of this contention is the difficulty, almost everywhere encountered, of re-establishing in their original locations the township, range, section, and quarter-section corners of the older public-land surveys of the United States. These old subdivision surveys practically constitute in themselves a series of co-ordinate systems. Had the original surveys all been made with the same degree of accuracy, there would be relatively little difficulty in re-establishing the original locations of lost corners from the bearings and distances alone. The principal difficulty is that the old surveys, many of them handled by incapable contractors without proper supervision or inspection, were not of uniform accuracy, and also that they had more than their share of blunders. It is obvious that, co-ordinated or not, accurate original land subdivision surveys would eliminate most of the modern surveyor's difficulties in re-establishing lost section corners.

---

[5] Chf. of Surveys, Maps and Surveys Div., TVA, Chattanooga, Tenn.

Another important point, from a public relations standpoint, is that surveyors should be careful to see that all published measurements and co-ordinates of the same course or point are in agreement. This has been stressed by A. H. Holt, M. Am. Soc. C. E.[6] To illustrate by a simple case, the writer saw considerable ridicule heaped on two reputable surveyors several years ago because they showed different distances for the same course on two adjoining record plats. The course in question was about 900 ft long; it was flat, open, and in every way conducive to accurate taping, and was the dividing line between two new building-lot subdivisions in a large Ohio city. Later investigation revealed that Surveyor A, whose tract was subdivided first, measured this course on a hot summer day, with his tape supported flat on the ground, and stretched under high tension. Surveyor B, whose tract was subdivided the following winter, measured the same course, at a temperature just a little above zero, with the tape suspended 2 or 3 ft above the ground, and stretched under relatively low tension. The two distances thus determined by the two surveyors differed by nearly 1 ft; yet both did accurate field taping. If the original field-computed distances had been corrected in the office for temperature, pull, and sag, the two final distances as determined by A and B would have agreed within a few hundredths of a foot. Publishing of the two uncorrected, different distances caused considerable confusion among, and ridicule from, public officials and others who had to use the two plats.

Philip Kissam,[7] **Assoc. M. Am. Soc. C. E.** (by letter).—There seems to be no question but that the methods involved in land transfer and land surveying records are in need of thorough revision. Co-operation between the engineering profession and the legal profession is essential if this objective is to be obtained. As Mr. Whitmore has stated, the Joint Committee may find that there is relatively little difference of opinion as to what should be done.

It may be remembered, however, that lawyers and engineers look at the problem from slightly different points of view. This results in a wide difference of opinion in regard to the purpose of land surveys and the requirements for land descriptions. The lawyer must have a survey and a description which identify the land. The engineer requires positive determination of the boundaries. At first glance these objectives may seem to be identical.

Suppose, for example, a residential lot were located in an area where the streets were not monumented but where there was a pair of arbitrarily placed survey control monuments for which the State plane co-ordinates had been determined accurately. To safeguard the title properly, the identity of the lot must be established. If street lines and distances from street intersections are mentioned (even if these lines are unmarked and quite indefinite), the lot is specifically identified. The streets mentioned and the rough location of the lots in the neighborhood are a matter of common knowledge; but, with such a description alone, the land surveyor cannot mark the boundaries. Thus such a description will satisfy the lawyer but not the engineer.

---

[6] "Trends in Boundary Surveying," by A. H. Holt, *Civil Engineering*, June, 1939, p. 359.

[7] Associate Prof. of Civ. Eng., Princeton Univ., Princeton, N. J.

To locate the property properly, the best procedure would be to include, in the description, ties to the control monuments. These ties alone, with the dimensions of the lot, would locate it specifically. However, the title examiner would be unable to assure himself that the lot so described was, in fact, the lot for which he was searching the title, and such a description, although satisfying the engineer, would not be acceptable to the lawyer.

From these divergent points of view, in the opinion of the writer, spring the chief difficulties encountered in land transfer to-day and the abortive attempts to rectify them. Aside from these considerations, however, basic agreement between the two professions is not too difficult to obtain.

Mr. Whitmore emphasizes the fact that an important difficulty preventing the improvement in land-transfer procedure is the inertia that must be faced which tends to maintain the same systems hitherto utilized. Difficult as it is to institute change, a beginning has certainly been made. The work under Mr. Whitmore's direction in the Tennessee Valley is one of the beginnings of such a change. His work is based on sound principles which will pay dividends in the future. Again, Carl M. Berry,[8] Assoc. M. Am. Soc. C. E., has described another cadastral survey at the Grand Coulee Dam, based on these sound principles. Naturally, the first changes toward better methods will be found in the work of larger organizations and governmental units. State highway departments and county and municipal governments will utilize better methods for property surveys. On the other hand, it is expected that the general adoption of sound methods will not occur very rapidly but rather will grow outward from the centers established by the larger organizations, both public and private.

The great difficulty which prevents the more rapid adoption of good methods of property transfer, in addition to the inertia mentioned by Mr. Whitmore, is the lack of machinery for recording, properly, the results of land surveyors' work in the areas where conflicting survey evidence exists. Frequently a land surveyor must, of necessity, develop a solution for a certain area containing many parcels in order to establish the location of one particular parcel. There is no governmental agency which records the results of his work; nor is there simple machinery to obtain adjudication of his conclusions so that his work may not be lost nor later challenged by another surveyor. With public recognition of his work properly recorded, there would be a permanence of location and a reduction of survey repetition. It will be necessary, therefore, not only to overcome inertia, and divergent points of view between lawyers and engineers, but also to develop methods for recording land surveying data.

DESIGN OF AN OPEN-CHANNEL CONTROL SECTION

BY KARL R. KENNISON,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. V. L. STREETER, EMERY H. WILLES, ROBERT O. THOMAS, FRANK S. BAILEY, GEORGE E. BARNES, AND KARL R. KENNISON.

SYNOPSIS

In designing an open channel to measure the flow of water, the shape of the controlling section to produce any desired rating curve can be determined by a definite mathematical relationship, the expression of which is claimed to be new, and to have possibilities in the application to practical problems. An analysis of the problem is contained in this paper. For example, if it is desired to modify a Venturi flume so that the rating curve at the given piezometer section immediately up stream from the controlling throat will be a predetermined convenient straight line, it can be done readily by the method presented herein. The writer first outlines the principles involved and arrives at mathematical expressions for the shape of the controlling section in terms of the desired rating, and then illustrates the application by the solution of specific problems.

INTRODUCTION

In any weir, flume, open nozzle, etc., it does not appear to be difficult to fit the dimensions of the controlling section to the desired rating curve by cut-and-try computations. However, the writer has frequently made designs of this character and has been intrigued by the observation that, even with precision so extreme that it seems unjustifiable, such cut-and-try computations do not give the true theoretical dimensions of the control. For example, at any depth of flow there may be identical velocities, with a great variety of section shapes, as long as the section areas are the same, excess width at one point being offset by decreased width at another. In fact, two controlling sections can be quite different in general appearance; that is, they can have a different relationship between depth and width and yet their two curves of

---

NOTE.—Published in May, 1939, *Proceedings*.

[1] Chf. Engr., Met. Dist. Water Supply Comm., Commonwealth of Massachusetts, Boston, Mass.

area, plotted against depth, can be so nearly alike that the resulting rating curves are the same within the precision expected in hydraulic computations. For this reason, cut-and-try computations fail to reveal the true theoretical shape of a controlling section required to produce a given rating curve, although they may solve any single specific problem with entire satisfaction so far as practical results are concerned.

The writer has long felt the need of a better understanding of the principles involved. His earlier attempts to obtain a correct analytic solution of the problem were discouraged by the mathematical complications encountered. A solution is presented herein which obtains the desired result—namely, simple expressions for the width and depth of the controlling section in terms of the given rating.

THEORETICAL SOLUTION

Referring to Fig. 1, it is required to find d_c and B_c in terms of the desired rating curve—that is, in terms of Q, d_p, S and the elements of the given piezometer section, or combinations of them, B_p, A_p, and H_p. The frictional loss, h_f, is relatively quite small and the first assumption in the interest of practical simplicity is to neglect it and to assume H_p equal to H_c in finding the expressions for d_c and B_c. It is practical as well as accurate and convenient to do this and to take the relatively small amount of friction into account later when finding the actual dimensions in any specific problem.

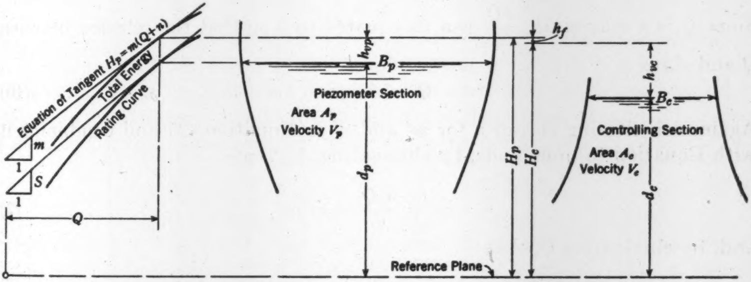

FIG. 1

Three general equations, applicable to any conditions and variations of flow, through any type of section, even through a section whose dimensions themselves are variable, are as follows:

$$Q = A_c V_c \quad \text{(1a)}$$

$$V_c = \sqrt{2 g h_{vc}} \quad \text{(1b)}$$

and,

$$h_{vc} = H_p - d_c \quad \text{(1c)}$$

A fourth general formula—

$$H_p = m (Q + n) \quad \text{(2)}$$

—requires the condition of critical flow through a given controlling section. Equation (2) also becomes general if m' and n' are substituted for m and n, such that

$$H_p = m' (Q + n') \quad \text{(3)}$$

Combining Equations (1) and (3):

$$\frac{Q^2}{2\,g\,A_c^2} = m'\,Q + m'\,n' - d_c \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

There are five variables in this general equation. To expedite the analysis, consider a continuous variation of flow, in a section of given dimensions, under a constant head H_p. When the desired critical depth d_c is reached, the discharge Q is at its maximum rate; and, m' and n' become m and n, which are constant because H_p is constant. Furthermore, in any given section the area varies with the depth and *vice versa*, and for present purposes one may assume d_c to be some function of A_c. Hence dd_c = (function of A_c) dA_c.

Accordingly, to determine the desired relationships in a controlling section, differentiate Equation (4), substituting m and n as constants instead of m' and n' and (function of A_c) dA_c instead of dd_c. As a result:

$$\frac{dQ}{dA_c} = \frac{Q^2 - f(A_c)}{A_c\,(Q - A_c^2\,g\,m)} \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

Since Q is a maximum, $\frac{dQ}{dA_c}$ can be equated to 0 so that the relation between Q and A_c is

$$Q = A_c^2\,g\,m \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

Again, substituting m and n for m' and n' in Equation (4) and combining it with Equation (6), one finds, by eliminating A_c, that

$$d_c = \frac{m\,Q}{2} + m\,n \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

and, by eliminating Q, that

$$A_c^2\,m^2\,g = 2\,(d_c - m\,n) \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

Since B_c is the differential of A_c with respect to d_c, one can differentiate Equation (8), m and n continuing constant as before; thus:

$$\frac{dA_c}{dd_c} = B_c = \frac{1}{A_c\,m^2\,g} \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

Combining Equation (9) with Equation (6) to eliminate A_c:

$$B_c = \frac{1}{\sqrt{m^3\,Q\,g}} \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

Thus Equations (7) and (10) are simple expressions for the depth and width at the controlling section, in terms of m and n; and the latter may be expressed in terms of the given rating curve and the elements of the given piezometer section as follows:

Since velocity head varies as the square of velocity, its rate of change is twice that of the velocity; and, since velocity varies as quantity discharged and inversely as area, its rate of change is the difference between those of the quantity and of the area. In other words

$$\frac{dh_{vp}}{h_{vp}} = \frac{2\,dV_p}{V_p} = 2\left(\frac{dQ}{Q} - \frac{dA_p}{A_p}\right) \dots\dots\dots\dots (11)$$

It is obvious that $dA_p = B_p\, dd_p$, and hence

$$\frac{dA_p}{dQ} = B_p \frac{dd_p}{dQ} = B_p\, S \dots\dots\dots\dots (12)$$

Since, by definition, $H_p = d_p + h_{vp}$; $\frac{dH_p}{dQ} = m$; and, $\frac{dd_p}{dQ} = S$:

$$m = S + \frac{dh_{vp}}{dQ} \dots\dots\dots\dots (13)$$

Combining Equations (11), (12), and (13) to eliminate the differentials:

$$m = S + 2\, h_{vp}\left(\frac{1}{Q} - \frac{B_p\, S}{A_p}\right) \dots\dots\dots\dots (14)$$

Also, by definition:

$$n = \frac{H_p}{m} - Q \dots\dots\dots\dots (15)$$

Thus, the values of the convenient intermediaries m and n are given in Equations (14) and (15), in terms of the desired rating curve and the known elements of the given piezometer section, which values of m and n may be substituted in Equations (7) and (10) to determine the precise theoretical shape of the controlling section necessary to produce the desired rating.

APPLICATION OF THEORY TO PRACTICE

It is obvious that the foregoing computations are based on a theoretically perfect condition, free from cross currents and eddies, in which the filaments of flow are horizontal, and the pressure proportional to the depth. A satisfactory condition in this respect will not be obtained at the throat of the controlling section if the latter is too short or its immediate approach too suddenly contracted. It is not the purpose of this paper to discuss the proper design of a contraction to produce a smooth horizontal flow. A sufficiently gradual section change to a throat or crest which is not too short in the direction of flow, together with a sufficient length of the critical throat section to straighten the filaments, will result in a condition of flow past the controlling section which approaches remarkably close to the perfection sought. For example, in the writer's experience, a properly designed, flat-crested, submerged weir is an extremely accurate measuring device and one which shows little if any difference between theoretical and actual rates of discharge. However, it is not the intention to disclaim the practical necessity of modifying the theoretical relationships by an empirical coefficient, since the principal purpose of this paper is to analyze and present these relationships.

CORRECTION FOR FRICTION

This practical necessity for an appreciable length of water travel between the piezometer section and the controlling section results in a certain frictional loss between the two. Such loss is relatively small and may be compensated for by constructing the entire measuring device on a slight slope. It is generally so small that rough computations and estimates of the weighted average hydraulic elements and coefficient of roughness will indicate the appropriate slope to be given to the invert or reference plane of the measuring device.

Although such a fixed slope will generally be sufficient to compensate for frictional losses, throughout the desired range of discharge rates, without material sacrifice of precision, a more complete and very precise compensation can best be made as follows: The foregoing rough computations and estimates will give the frictional loss or slope of the total-energy gradient between the piezometer section and the controlling section for different rates of discharge. In a device of the type under discussion, this slope will be fairly constant throughout a considerable range of the lower rates of discharge but will increase noticeably at the higher rates. Hence one may select, arbitrarily, a fixed slope for the invert or reference plane which will compensate for the frictional loss at the lower rates of discharge, so that only at the higher rates of discharge must the extra head loss, h_f, or difference between H_p and H_c, be accounted for. The easiest and most satisfactory way to do this is to plot a curve of the roughly computed values of h_f for different values of Q from which the slope, $\frac{dh_f}{dQ}$, as well as h_f, can be read for any value of Q. To make the correction for excess frictional loss, subtract h_f from H_p and $\frac{dh_f}{dQ}$ from m. Equation (14) then becomes

$$m = S + 2\,h_{vp}\left(\frac{1}{Q} - \frac{B_p\,S}{A_p}\right) - \frac{dh_f}{dQ} \quad \text{.............} (16)$$

and Equation (15) becomes

$$n = \frac{H_p - h_f}{m} - Q \quad \text{....................} (17)$$

If friction is neglected (that is, if one does not wish to use expressions to which corrections for excess frictional loss at the higher rates of flow can be applied as described herein) Equations (7), (10), (14), and (15) can be combined to obtain the dimensions of the critical section in terms of the desired rating curve and of the known elements of the given piezometer section, without using the values of m and n. Thus, for the drop in water level between the piezometer section and the controlling section:

$$d_p - d_c = Q\,S\left(\frac{1}{2} - \frac{h_{vp}\,B_p}{A_p}\right) \quad \text{...............} (18)$$

The width of the controlling section can be expressed similarly, but the equation would be too complicated to warrant its use instead of Equations (10) and (14).

ILLUSTRATIVE EXAMPLES

Example 1.—In Fig. 2, a piezometer section is chosen arbitrarily, as an example, with a 3-ft bottom width, a 3-ft depth and side slopes of 4 on 1.

The rating curve is also chosen arbitrarily as a straight line, the maximum discharge being 28.3 cu ft per sec. Of course, such a line must show, at all points, a definitely greater depth, less discharge, than could pass the piezometer section itself as a controlling section. Otherwise, because of the well-understood tendency toward the propagation of surface waves, a definite relation between rate of discharge and depth at the piezometer section would not be assured at the lesser depths. To insure this condition the invert, in this example, is arbitrarily raised 0.1 ft at the controlling section (see Fig. 2), and the straight-line rating is drawn tangent to the rating curve which this raised invert causes at these lesser depths.

FIG. 3

To illustrate the application of the correction for excess friction, as well as its smallness, the velocities and hydraulic elements were computed at different depths in the case of this open nozzle. They indicated that the invert or reference plane should be on a slope of about 0.0019 to compensate for the frictional losses at the lesser depths, and that at the greater depths the excess friction, h_f, to be subtracted from H_p, and its rate of change, $\frac{dh_f}{dQ}$, to be subtracted from m, are approximately as shown by the supplementary graph in Fig. 3(*a*). These corrections have been applied as shown in the parentheses in Table 1 and result only in a slight widening of the upper part of the controlling section, as shown by the dotted line in Fig. 3(*b*).

[2] "Sutro Weir Investigations Furnish Discharge Coefficients," by F. T. Mavis, M. Am. Soc. C. E., E. Soucek, Jun. Am. Soc. C. E., and H. E. Howe, *Engineering News-Record*, November 12, 1936, p. 679.

[3] *Journal*, Boston Soc. of Civ. Engrs., January, 1934.

The exact shape of the controlling section becomes relatively less important as the depth d_c increases. The result is that, although a circular piezometer section, closed at the top, results in the peculiar theoretical shape of the top of the controlling section shown in Fig. 3(*b*), the omission of this sharp irregularity, and the substitution of any convenient arbitrary extension of the sides of the controlling section, merely results in a negligible gradual departure from the straight-line rating at depths greater than 95% of the diameter. The maximum departure at full pipe is only about one-third of 1% increase in the rate of discharge.

CONCLUSION

The depth and width at the controlling section given by Equations (7), (10), and (18) are those which, if adhered to throughout the entire range of discharge, or depth, will result in the desired rating. This does not mean that in any particular limited case another set of dimensions determined, for example, by an approximate cut-and-try computation, will not fill the specifications satisfactorily. However, the section dimensioned by these formulas is the only one that will be theoretically correct throughout the entire range of depths; and, a knowledge of the theoretically correct shape cannot fail to contribute to good design in the selection of dimensions to fit the conditions in any case. There are undoubtedly other adaptations than those illustrated herein.

DISCUSSION

V. L. Streeter,[4] **Assoc. M. Am. Soc. C. E. (by letter).**—The theoretical solution for an open-channel control section, presented in this paper, will be of value to the designing engineer. The writer, however, found the derivation difficult to understand, particularly as to how Equation (2) requires the condition of critical flow, and why the denominator, instead of the numerator, of Equation (5) is set equal to zero for maximum discharge. Although the theoretical solution given by the author results in correct final equations, the two foregoing points so obscured the derivation that the writer attempted to find a more simple solution. For example, combining Equations (1),

$$\frac{Q^2}{2\,g\,A_c^2} = H_p - d_c \qquad (19)$$

As critical flow requires maximum discharge for a given available energy head, Equation (19) will be differentiated with respect to A_c, considering H_p a constant; thus

$$\frac{Q\,dQ}{g\,A_c^2\,dA_c} - \frac{Q^2}{g\,A_c^3} = -\frac{dd_c}{dA_c} \qquad (20)$$

Setting $\frac{dQ}{dA_c}$ equal to zero for maximum Q, a critical flow relation results; thus:

$$\frac{dd_c}{dA_c} = \frac{Q^2}{g\,A_c^3} \qquad (21)$$

As $B_c\,dd_c = dA_c$, Equation (21) contains the two unknowns B_c and A_c. To determine another relationship involving the two unknowns, differentiate Equation (19) with respect to Q, with H_p a variable. Then:

$$\frac{dH_p}{dQ} = \frac{Q}{g\,A_c^2} - \frac{Q^2}{g\,A_c^3}\,\frac{dA_c}{dQ} + \frac{dd_c}{dQ} \qquad (22)$$

Eliminating dd_c in Equations (21) and (22):

$$\frac{dH_p}{dQ} = \frac{Q}{g\,A_c^2} \qquad (23)$$

which contains one unknown, A_c. Equations (21) and (23) are equivalent to Equations (10) and (6), as $\frac{dH_p}{dQ} = m$. When the desired rating curve is given in the form:

$$d_p = f_1(Q) \qquad (24)$$

and

$$A_p = f_2(d_p) = f_2[f_1(Q)] \qquad (25)$$

---

[4] Associate Engr., U. S. Section, International Boundary Comm., U. S. and Mexico, El Paso, Tex.

(in which f_1 and f_2 are known functions) $\frac{dH_p}{dQ}$ may be determined from:

$$\frac{dH_p}{dQ} = \frac{Q}{g\,A_p^2} - \frac{Q^2}{g\,A_p^3}\,\frac{dA_p}{dQ} + \frac{dd_p}{dQ} \ldots\ldots\ldots\ldots\ldots (26)$$

for any value of Q. Equation (26) is Equation (22) with Subscript c replaced by Subscript p.

In designing the control, Equations (19), (21), (23), and (26) are needed. From Equation (26) $\frac{dH_p}{dQ}$ is determined for several values of Q throughout the range of capacity of the structure. With these values of $\frac{dH_p}{dQ}$, A_c is found from Equation (23), and with A_c known, values of $\frac{dd_c}{dA_c} = \frac{1}{B_c}$ are found from Equation (21). Corresponding values of d_c are obtained from Equation (19).

If friction is to be taken into account, it may be estimated for the length of travel between the piezometer section and control section, for various discharges, thus:

$$h_f = f_3(Q) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (27)$$

Equation (23) then becomes:

$$\frac{dH_p}{dQ} - \frac{dh_f}{dQ} = \frac{Q}{g\,A_c^2} \ldots\ldots\ldots\ldots\ldots\ldots (28)$$

and Equation (19):

$$\frac{Q^2}{2\,g\,A_c^2} = H_p - h_f - d_c \ldots\ldots\ldots\ldots\ldots\ldots (29)$$

Equations (21) and (26) remain the same.

EMERY H. WILLES,[5] JUN. AM. SOC. C. E. (by letter).—The author needs to be commended on his unique approach to a problem, which, due to the mathematical complicity at first encountered, leads the pioneer investigator to despair of finding a simple theoretical solution. However, by expressing the width B_c and the depth d_c of the controlling section in terms of the slope m and intercept n of the tangent to the total energy-curve, followed, in turn, by expressing m and n in terms of the slope S of the rating curve and the known elements of the piezometer section, the author has presented a simple and effective solution to this seemingly non-solvable problem.

The writer, however, is unable to follow the author from Equation (5) to Equation (6). It is obvious from Equation (5) that $Q^2 - f(A_c) = 0$; also from Equation (6) that $Q - A_c^2\,g\,m = 0$. Then, by substitution, Equation (5) becomes the indefinite relationship $\frac{0}{0} = 0$. Equation (6) may also be obtained if $\frac{dQ}{dA_c} = \infty$ instead of 0. Thus, since $\frac{1}{\infty} = 0$, $\frac{A_c\,(Q - A_c^2\,g\,m)}{Q^2 - f(A_c)} = 0$; and, $Q = A_c^2\,g\,m$. This is very perplexing and led the writer to investigate $f(A_c)$

---

[5] Hydrographer, Utah Copper Co., Salt Lake City, Utah.

in Equation (5) as follows: Referring to Equation (4)

$$\frac{1}{2\,g}\left(\frac{2\,A_c^2\,Q\,dQ - 2\,Q^2\,A_c\,dA_c}{A_c^4}\right) = m\,dQ - dd_c = \frac{A_c\,Q\,dQ - Q^2\,dA_c}{g\,A_c^3} \quad \ldots (30)$$

Simplifying, and solving for $\frac{dQ}{dA_c}$, $\frac{dQ}{dA_c} = \frac{Q^2 - g\,A_c^3\,\frac{dd_c}{dA_c}}{A_c\,(Q - A_c^2\,g\,m)} = 0$; and,

$$Q = \pm\sqrt{g\,A_c^3\,\frac{dd_c}{dA_c}} \quad \ldots\ldots (31)$$

In any section $dA_c = B_c\,dd_c$; hence

$$\frac{dd_c}{dA_c} = \frac{1}{B_c} \quad \ldots\ldots (32)$$

and

$$Q = \sqrt{\frac{g\,A_c^3}{B_c}} \quad \ldots\ldots (33)$$

The foregoing investigation is leading the writer no nearer Equation (6) or the final solution. Therefore, since the author's solution revolves around Equation (6), the writer presents the following derivation: From Equations (1*c*) and (2)

$$Q = \frac{H_p}{m} - n = \frac{h_{vc} + d_c}{m} - n \quad \ldots\ldots (34)$$

and, because m and n are constant at the critical section, $dQ = \frac{dh_{vc} + dd_c}{m}$; and,

$$\frac{dQ}{dA_c} = \frac{1}{m}\left(\frac{dh_{vc}}{dA_c} + \frac{dd_c}{dA_c}\right) \quad \ldots\ldots (35)$$

From Equations (1*a*) and (1*b*): $h_{vc} = \frac{V_c^2}{2\,g} = \frac{Q^2}{2\,g\,A_c^2}$; and, $Q^2 = 2\,g\,h_{vc}\,A_c^2$. Furthermore, $2\,Q\,dQ = 4\,g\,h_{vc}\,A_c\,dA_c + 2\,g\,A_c^2\,dh_{vc}$; and,

$$\frac{dQ}{dA_c} = \frac{g\,A_c\left(2\,h_{vc} + A_c\,\frac{dh_{vc}}{dA_c}\right)}{Q} \quad \ldots\ldots (36)$$

Combining Equations (35) and (36) and solving for Q:

$$Q = \frac{m\,g\,A_c\,(2\,h_{vc}\,dA_c + A_c\,dh_{vc})}{dh_{vc} + dd_c} \quad \ldots\ldots (37)$$

From Equations (1*a*), (1*b*), and (1*c*) $H_p = d_c + h_{vc} = d_c\,\frac{V_c^2}{2\,g} = d_c + \frac{Q^2}{2\,g\,A_c^2}$; $Q^2 = 2\,g\,(H_p\,A_c^2 - A_c^2\,d_c)$; and, since H_p is assumed constant, $2\,Q\,dQ = 2\,g\,(2\,H_p\,A_c\,dA_c - 2\,A_c\,d_c\,dA_c - A_c^2\,dd_c)$. Finally, at the critical section, $\frac{dQ}{dd_c} = \frac{g}{Q}\left(2\,H_p\,A_c\,\frac{dA_c}{dd_c} - 2\,A_c\,d_c\,\frac{dA_c}{dd_c} - A_c^2\right) = 0$; and, solving for H_p:

$$H_p = A_c\left(\frac{2\,d_c\,\frac{dA_c}{dd_c} + A_c}{2\,A_c\,\frac{dA_c}{dd_c}}\right) = d_c + \frac{A_c}{2}\,\frac{dd_c}{dA_c} \quad \ldots\ldots (38)$$

From Equation (32) $\frac{dd_c}{dA_c} = \frac{1}{B_c}$; and, $H_p = d_c + \frac{A_c}{2\,B_c}$. Combining with Equation (1*c*):

$$h_{vc} = \frac{A_c}{2\,B_c} \quad \text{.......................} (39)$$

Writing the differential equation of Equation (39):

$$dh_{vc} = \frac{1}{2}\left(\frac{B_c\,dA_c - A_c\,dB_c}{B_c^2}\right) = \frac{1}{B_c}\left(\frac{dA_c}{2} - \frac{A_c}{2\,B_c}\,dB_c\right)$$

$$= \frac{1}{B_c}\left(\frac{dA_c}{2} - h_{vc}\,dB_c\right) \quad \text{.......................} (40)$$

Combining Equations (32), (37), (39), and (40), and solving algebraically for Q:

$$Q = \frac{m\,g\,A_c^2\left(\frac{3}{2}\,dA_c - h_{vc}\,dB_c\right)}{\frac{3}{2}\,dA_c - h_{vc}\,dB_c} = m\,g\,A_c^2 \quad \text{..........} (41)$$

ROBERT O. THOMAS,[6] JUN. AM. SOC. C. E. (by letter).—Considerable credit is due the admirable analysis made by the author. The writer is constrained, however, to offer a few criticisms and suggestions with a view to a more complete understanding of the hydraulic action of a control such as has been proposed. To that end the following equations are presented, using only one intermediary, *m*, to determine the elements of the control section:

$$d_c = H - \frac{m\,Q}{2} \quad \text{.......................} (42)$$

$$B_c = \frac{0.249\,\sqrt{H_p - d_c}}{Q\,m^2} \quad \text{.......................} (43)$$

$$m = \frac{S\,(A_p - 2\,B_p\,h_{vp})}{A} + \frac{V}{A\,g} \quad \text{.................} (44)$$

or,

$$m = S + \frac{2\,h_{vp}}{Q}\,(1.00 - V_p\,B_p\,S) \quad \text{..............} (45)$$

The use of Equations (42) to (44) will require less computation than those given in the paper.

The mathematical correctness of the method proposed by the author is beyond question, but the writer entertains doubts as to the practical feasibility in the use of such a control. Analysis of the flow through the control and in the channel above the control leads to the conclusion that the incorporation of such a design would seriously affect the conditions of flow in the canal. It is a condition of the design that the total energy head on the moving water prism shall be the same, neglecting friction, at the piezometer section and at the control. Since the flow through the control is at critical depth, this condition definitely establishes the water surface at both points. It is also a condition of the design that the canal shall carry less water than it otherwise would, if the control station were omitted. This condition alone leads to the conclusion that the channel could not be designed economically, because the cross-section would, of necessity, be larger than would ordinarily be required to convey the given flow.

---

[6] Junior Engr., Rapid Transit Design, City Engr. Office, Los Angeles, Calif.

However, the principal difficulties in the design arise in the section of channel which lies above the rating station. The elevation of the water surface at the piezometer section is not that which can be maintained in the channel above, due to the fact that the flows and depths at this section are not those which would result from uniform flow. Assuming a concrete-lined channel, with "n" equal to 0.014, Table 2 (Column (3)) gives the slopes necessary to maintain a uniform flow in the channel above the piezometer section.

TABLE 2.—CHANNEL SLOPE NECESSARY TO MAINTAIN UNIFORM FLOW

0.40	1.65	0.042	0.442	0.455

* n denotes uniform flow, and p denotes flow at the piezometer section.

Since it is a requisite, for the proper functioning of the control, that the channel be built so that the depth for any flow, at the piezometer section, will be greater than the depth for uniform flow, it is obvious that the slope must be greater than any calculated slope in Table 2. The effect of this will be to cause a backwater curve extending up stream from the piezometer section to the section of uniform flow.

The writer has assumed a slope of 0.0012, with n equal to 0.014, for the purposes of illustration. Table 3 gives the hydraulic elements as computed with these constants for the flows in Table 2.

For the larger flows there will be a considerable drop in the water surface in passing up stream from the piezometer section. The maximum flow that can pass the control section utilizes only a portion of the channel capacity after uniform flow is attained. The channel, as designed on this slope, would carry a maximum flow of 43.5 cu ft per sec, in uniform flow with a depth of 3 ft. The efficiency of the channel, therefore, is only $\frac{28.3}{43.5}$, or 65 per cent. It is the writer's contention that the construction of a channel that can only be utilized for a portion of its design capacity, due to the existence of a bottleneck at the point of flow measurement, is not economical.

Inasmuch as such devices as the Parshall flume[7] and the control meter developed by Julian Hinds,[8] M. Am. Soc. C. E., will accomplish the same purpose with little interference, if any, with the flow of water in the channel above the control, the writer favors their use, especially so because of the ease and accuracy with which flow conditions in the main channel may be predicted.

The writer is of the opinion that the convenience of a straight-line relationship between depth and discharge is not sufficient to justify the uneconomic over-design of the channel section which is necessitated by its use.

Frank S. Bailey,[9] Assoc. M. Am. Soc. C. E. (by letter).—The author seems to have assigned himself a difficult task and performed it very ingeniously. The writer's first impression of this paper was that it was too complicated for his understanding and possibly in this case the first impression was the best. However, during a leisure hour he began trying to follow the author's reasoning and to check the equations he has derived.

Becoming puzzled over Equation (6) he wrote a letter of inquiry to the author, who replied courteously:

> "* * * if (5) is equated to 0, we find that this equation is satisfied if any of the factors are equated to 0. In other words, $Q - A_c^2\,g\,m = 0$. I did not think it necessary to call attention to the other mathematical possibilities which have no practical significance to our problem, for example when $A_c = 0$."

Although it is probably true, as Mr. Kennison states, that $Q - A_c^2\,g\,m = 0$, the writer has not found why it must be so. He believes that

$$Q^2 - g\,A_c^3\,f'(A_c) = 0 \qquad (46a)$$

and that

$$Q^2 = \frac{g\,A_c^3}{B_c} \qquad (46b)$$

Equation (5), obtained by differentiating Equation (4), could read

$$\frac{dQ}{dA_c} = \frac{Q^2 - g\,A_c^3\,f'(A_c)}{A_c\,(Q - A_c^2\,g\,m)} \qquad (47)$$

in which $f'(A_c)$ signifies the derivative of $f(A_c)$ with respect to A_c. Perhaps Equation (5) is just as valid; but Equation (47) seems more complete. Referring[10] to Fig. 4, it is evident that $\Delta A_c = B_c\,\Delta d_c$; and, in the limit, $\frac{dd_c}{dA_c} = \frac{1}{B_c}$, which is the derivative of $f(A_c)$. Therefore, placing the numerator of Equation (47) equal to zero, the relation between Q and A_c is as given by Equation (46b).

As to the propriety of having a factor in the denominator which equals zero: As the numerator must equal zero to satisfy Equation (5) if the denominator is also zero it seems that the value of the fraction becomes $\frac{0}{0}$ which is generally indeterminate, although not always. In any event no factors in the denominator must, of necessity, be equal to zero, as the denominator may have almost any value and still satisfy the requirement for a maximum value of Q that $\frac{dQ}{dA_c} = 0$, if the numerator is zero.

[10] "Handbook of Hydraulics," by Horace Williams King, McGraw-Hill Book Company, Inc., New York and London, Third Ed. (1939), p. 373.

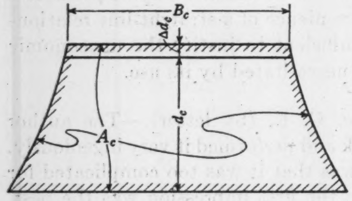

FIG. 4

Horace W. King, M. Am. Soc. C. E., describes the formula

$$\frac{a^3}{T} = \frac{Q^2}{g} \qquad (48)$$

as "a general criterion, applicable to all channels, indicating the relation between cross-section and discharge which must exist in order that flow may occur at critical depth."[10] Equation (48) resolves to

$$Q^2 = \frac{g\,A_c^3}{T_c} \qquad (49)$$

and is identical with Equation (46*b*) if $f'(A_c) = \frac{1}{T_c}$, T_c being the top width of the cross-section of the stream at the control section.

The writer has made a rough calculation of the area A_c, corresponding to a flow Q of 28.3 cu ft per sec, by using values given for d_c and B_c in Table 1(*a*). In this calculation it was assumed that the sides of the section in Fig. 2 were straight between the d_c-intervals. As the sides are curved, the value of 3.34 sq ft, obtained for A_c, is a little too large.

If this value is used in Equation (48), the resulting numerical expression is $\frac{(3.34)^3}{1.092} = \frac{(28.3)^2}{32.2}$, or $34.1 = 24.9$, which does not fulfil the requirements of the formula, as the two sides should be equal. If the precise value of A_c is found to be very close to 3.00 (which is probably the case), Equation (48) would check exactly and would be a proof of the correctness of Mr. Kennison's results.

GEORGE E. BARNES,[11] M. AM. SOC. C. E. (by letter).—On the subject of open-channel control sections, the author is to be credited with: (1) Definition of the problem in general terms amenable to analysis, (2) development of the topic by several original steps, and (3) valid conclusions and results, including certain derived equations of useful form.

Unfortunately, the validity of the author's derived equations is not established by the methods followed in the paper. Equations (7), (10), (14), and (15) depend on Equation (6). The writer challenges the author to defend his derivation of Equation (6) on the basis of the reasoning given in the paper—

---

[11] Prof., Hydr. and San. Eng., and Head, Dept. of Civ. Eng., Case School of Applied Science, Cleveland, Ohio.

namely, "Since Q is a maximum, $\frac{dQ}{dA_c}$ can be equated to 0 so that the relation between Q and A_c is $Q = A_c^2\, g\, m$."

Relative to the foregoing, the following comments are pertinent: If, as the author states, Q is made to vary under constant H_p, the resulting curve (see Fig. 5) is of such form that Q becomes a maximum at some particular value of d, designated as the critical depth. Since $\frac{dQ}{dd}$ or $\frac{dQ}{dA}$ is known to be continuous and is known to change in sign from plus to minus at the point of critical depth, the slope of the tangent to the curve at that point is zero. Therefore, the numerator of the right-hand side of Equation (5) is equal to zero when the denominator is not zero. However, if both numerator and denominator are zero at d_c, further investigation of the nature of Q as a function of A_c is necessary. The author's assumption that the denominator is equal to zero cannot be accepted without adequate proof. Lacking such proof, the correctness of the succeeding equations is open to question.

The method used by the writer to determine the author's equations is as follows: In any open channel of whatever cross-section, the elevation of the energy gradient above the channel bed is $H = h_v + d$ (see Fig. 6). For any particular value of Q the channel proportions for which H is a minimum (flow at critical depth) are found thus:

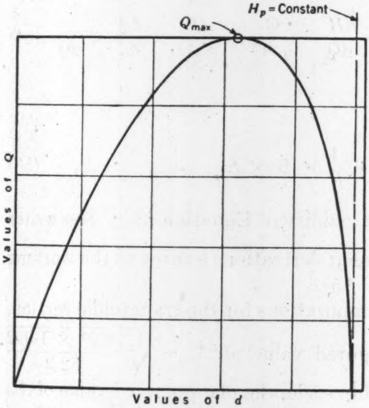

FIG. 5

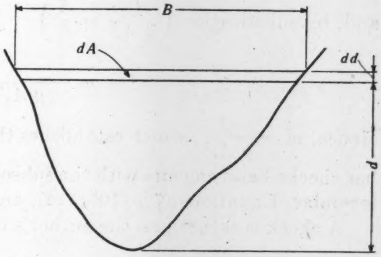

FIG. 6

$$H = \frac{Q^2}{2\,g\,A^2} + d \quad \text{.......................} (50)$$

$$\frac{dH}{dd} = -\frac{Q^2}{g\,A^3} \times \frac{dA}{dd} + 1 = 0 \quad \text{.................} (51)$$

but $\frac{dA}{dd} = B$; hence

$$Q^2 = \frac{g\,A_c{}^3}{B} \qquad \text{(52}a\text{)}$$

and

$$\frac{Q^2}{2\,g\,A_c{}^2} = \frac{A_c}{2\,B} \qquad \text{(52}b\text{)}$$

Referring to Fig. 1—by construction

$$d = H - \frac{Q^2}{2\,g\,A^2} = m'\,Q + m'\,n' - \frac{Q^2}{2\,g\,A^2} \qquad \text{(53}a\text{)}$$

By definition, the slope of the rating curve is

$$S = \frac{dd}{dQ} \qquad \text{(53}b\text{)}$$

and, by definition, the slope of the depth versus energy-head curve is

$$m' = \frac{dH}{dQ} \qquad \text{(53}c\text{)}$$

Then, differentiating Equation (53*a*),

$$\frac{dd}{dQ} = \frac{dH}{dQ} - \frac{Q}{g\,A^2} + \frac{Q^2}{g\,A^3} \times \frac{dA}{dQ} = \frac{dH}{dQ} - \frac{Q}{g\,A^2} + \frac{Q^2}{g\,A^3} \times \frac{dA}{dd} \times \frac{dd}{dQ} \qquad \text{(54)}$$

and, by substitution $\left(\frac{Q^2}{g\,A_c{}^3} = \frac{1}{B}\right)$:

$$S = m - \frac{Q}{g\,A_c{}^2} + \frac{1}{B} \times B \times S \qquad \text{(55)}$$

Hence, $m = \frac{Q}{g\,A_c{}^2}$, which establishes the validity of Equation (6). The writer has checked and concurs with the subsequent derivations leading to the working formulas, Equations (7), (10), (14), and (15).

A check is secured on the author's computations for the trapezoidal section, at peak discharge, as follows: The required value of $A_c = \sqrt[3]{\frac{28.3^2 \times 1.092}{32.2}}$ $= 3.01$. If the control section is plotted to scale, the planimetered value of A_c, as drawn, will be found to agree. It follows also that the computed value of $h_{vc} + d_c = H_p$ (Equation (1*c*)), which proves to be the case, provided that the reference plane for both control and piezometer sections is taken at the bottom of the piezometer section for the values shown in Table 1.

The writer would also like to comment on certain matters touched upon in the paper, bearing on applications of the method and practical considerations.

A control section is one at which the minimum energy head for any discharge is independent of the energy head down stream. The particular control section to be adopted for any given case depends first on the function it is to perform. One common function of a control section is the measurement of discharge;

another, perhaps less common, is that of regulating velocities up stream. With intelligent design, it is possible to combine the two functions in one structure, although the requirements for one do not necessarily meet the requirements for the other. In the matter of measurement, sensitivity of the water-surface level with respect to discharge is important. In the matter of velocity regulation, not only is the average velocity up stream of importance, but the effect of the control section on velocity distribution up stream may be important as well. Frequently, the necessity of conserving head has considerable influence on the selection of a suitable control section. The author's statement that his method "is claimed * * * to have possibilities in the application to practical problems" is a modest one. The writer believes that the author's paper, if read with understanding, will do much to offset a tendency, sometimes noted, toward the adoption of accepted types of control sections, after only superficial investigation, in situations where an original design is much to be preferred.

In the general case, when flow is at critical depth, the velocity head is half the average depth (see Equation (52*b*)), and the energy head at the control section is $1.5\, d_{\text{average}}$. Of course, this is H_p minus losses. Where both the control section and the up-stream sections are of regular geometric shape, the equation, $H_p = H_c +$ losses, expressed in terms of the variables including d_c, may be set up without great difficulty. However, except for the very simplest cases, its solution may be too complicated for handling except by "cut-and-try" methods. The writer has had occasion to design control sections for grit

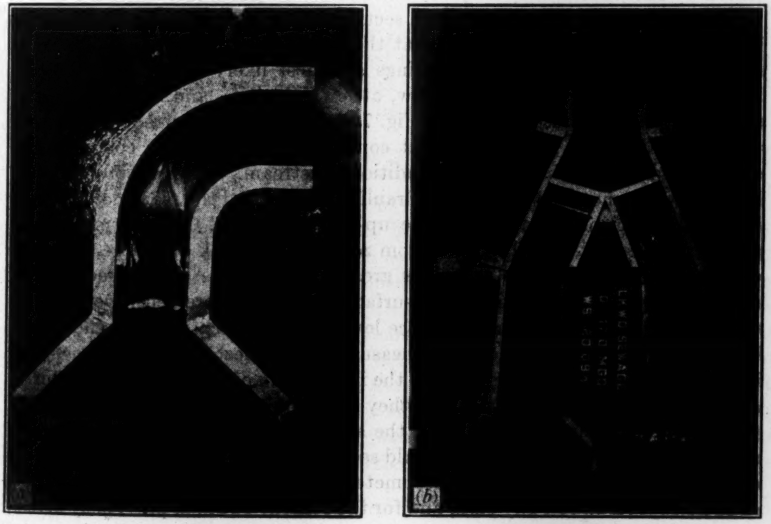

Fig. 7.—Flow in Control Sections Designed for Grit Chambers (Model Scale 1 : 6)— (a) Ward's Island, New York, N. Y. (Flow Equivalent to 86 Cu Ft per Sec); (b) Lakewood, Ohio (Flow Equivalent to 26 Cu Ft per Sec)

chambers for the purpose of measuring discharge, or for regulating velocities, or both (see Fig. 7). In such cases, the velocity head in the grit chamber is so small as to be practically negligible, and the difference in water-surface elevation between the control section and the up-stream section may be taken as the velocity head at critical depth in the control section, plus the head loss in the transition. The head loss in the transition may be quite closely estimated, or, if necessary, determined by experiment, as a function of this velocity head. The following simplified equation may then be written:

$$Z_g = Z_c + d_c + (1 + k)\, h_{vc} \ldots\ldots\ldots\ldots\ldots\ldots (56)$$

in which Z_g = the water-surface elevation in the grit chamber, and Z_c = invert elevation in the control section. It is important to note in this connection that conditions may permit designing the up-stream section to fit a suitable control section, as an alternate to the more obvious procedure of designing the control section with respect to the up-stream section. By arbitrary proportioning of the control section and the up-stream section, suitable design for a given range of flows often may be secured with readiness.[12] Such cut-and-try methods, as stated by the author, may be just as useful and important as others.

If the performance of the control section is to be measured, it will probably be with piezometers located either at the up-stream section or at the control section, or both. Piezometer readings are most likely to be accurate when taken in sections of undisturbed flow, at low velocities, and in the absence of standing waves or cross currents. Fig. 7 illustrates the occurrence of standing waves in the throat of two different control sections, and the comparatively smooth and undisturbed surface condition up stream. Thus there is likely to be better agreement between the hydraulic gradient and the piezometer reading when observations are taken at the up-stream section. Furthermore, for a given rating curve with Q varying from zero to some peak discharge, the range of depth in the up-stream section is greater than at the control section, and consequently the up-stream water-surface level is a more sensitive indicator than the control section water-surface level. In some cases, adherence to the belief that critical depth can be measured with piezometers at some point in the control section has resulted in the installation of open-channel measuring devices which are less sensitive than they might be with the piezometers located up stream. Throughout his paper, the author refers to the up-stream section as the piezometer section. This would seem to imply, although it is not specifically stated, that the location of piezometers in the up-stream section is desirable or to be expected. In any case, and for the reasons outlined previously herein, the writer would recommend strongly that, in the usual situation, piezometer readings be taken up stream rather than at the control section.

The writer is not quite clear as to the author's statement that the reason for raising the invert of the channel at the control section by some arbitrary amount is to offset any tendency toward surface waves. Of course, it is necessary to raise the invert, or otherwise to constrict the control section, to insure that there is a localized break in the hydraulic gradient. Otherwise the true location of the control section would not be known so accurately. The author does not point out other means for constricting the control section which are perhaps equally suitable. In the writer's experience, it has often been preferable to reduce the width of the control section all the way from floor level to free-board level with, or without, raising the invert.

---

[12] "Unique Solution for Grit Chamber Design," by George E. Barnes, *Waterworks and Sewerage*, September, 1939.

The author limits the scope of his paper to a precise statement of the theory involved and a short discussion of some practical applications. Any further discussion by the writer of practical considerations would be beyond the limits of the paper as written. The paper is remarkably comprehensive, considering its brevity, and is written with an accurate conception of the practical aspects of the subject.

KARL R. KENNISON,[13] M. AM. SOC. C. E. (by letter).—There is a reasonable unanimity among the various discussions as to the correctness of the theory advanced and conclusions reached. It is evident that the writer's aversion to the publication, in *Proceedings*, of lengthy details of mathematical equations has gotten him into difficulties and led to the expenditure of much time and effort by those discussing the paper which might have been avoided.

Prior to its last-minute hasty revision, the paper contained the following explanation of the method of finding Equation (6), which should meet, satisfactorily, the criticism properly aimed at the explanation as published: Combining Equations (1) and (2), Equation (4), adapted to the condition of critical flow through the controlling section, becomes

$$\frac{Q^2}{2\,g\,A_c^2} = m\,Q + m\,n - d_c \ldots\ldots\ldots\ldots\ldots\ldots (57)$$

There are five variables in Equation (57), but m and n are constant for small or differential changes in the others and hence do not affect, other than as constants, the relation which it is desired to find between the other three. One of the conditions that makes the section a controlling or critical section is that, for any one value of the variable depth d_c and with the same relation between all the variables and this tentatively constant depth, the area A_c must be the minimum area that will satisfy the equation; because if any smaller area at such constant depth could discharge as much as the rating curve calls for, then A_c is too large. That is, some other smaller critical section must be holding the water back. Accordingly, for present purposes, one may: Tentatively consider m, n, and d_c as constants; differentiate Equation (57) with respect to the variables Q and A_c; and—since A_c is a minimum and $\frac{dA_c}{dQ}$ equal to 0—write:

$$\frac{dA_c}{dQ} = \frac{A_c}{Q} - \frac{A_c^3\,g\,m}{Q^2} = 0 \ldots\ldots\ldots\ldots\ldots\ldots (58)$$

Hence (see Equation (6)) $Q = A_c^2\,g\,m$. The independent proofs developed in the discussion, such as that of Mr. Willes and Mr. Barnes, are very gratifying.

Mr. Streeter questions why Equation (2) requires the condition of critical flow. This is because it involves m and n which, by definition, are tied to the rating curve of the controlling section. In other words, they apply to the condition of critical flow through the controlling section.

---

[13] Chf. Engr., Met. Dist. Water Supply Comm., Commonwealth of Massachusetts, Boston, Mass.

It is impossible for the writer to follow the reasoning of Mr. Thomas in his criticism that the use of such a controlling section precludes an economical approach channel. Whatever the maximum discharge of the economically designed channel is—whether 28.3 cu ft per sec or 43.5 cu ft per sec—this is, of course, what determines the maximum capacity of the controlling section, or the upper end of the desired rating curve. The slope of the rating curve must fit the conditions of available head. If there is a dearth of available head for the measurement, then the rating curve must be correspondingly flat. Within the range of desired flows there will be times when there is some non-uniform flow or back-water curve; but this should not affect the economical design of the main channel in any way, and any special modification of this channel that might be needed would be confined to a very short length immediately up stream from the piezometer section.

Answering some of the inquiries by Mr. Barnes: It is true, and should be stated definitely, that the location of the piezometers is in the up-stream section. If they were near the control section, recording would be erratic and unpredictable, because, when flow is nearly at the critical depth, the upper and lower alternative stages are so close together that the surface jumps easily from one to the other in waves. For the lower rates of flow, in the practical examples given for illustration, this tendency would extend up stream to the piezometer section if the invert at the control section were not raised to prevent it. The accurate recording of a water surface depends on forcing the alternative stages apart from each other. As Mr. Barnes points out the same thing could be done by reducing the width instead of raising the invert. However, the latter was better adapted to the examples given which sought a straight-line rating curve of maximum steepness.

In conclusion the author is gratified to note an appreciation of the comprehensive character of this study and of its adaptation to practical aspects.

GRAPHICAL ARCH ANALYSIS APPLICABLE TO ARCH DAMS

BY CARL H. HEILBRON, JR.,[1] ASSOC. M. AM. SOC. C. E., AND
WILLIAM H. SAYLOR,[2] JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. I. M. NELIDOV, AND CARL H. HEILBRON, JR. AND WILLIAM H. SAYLOR.

SYNOPSIS

In this paper is presented a system, mostly graphical, for analyzing unsymmetrical fixed-end arches of variable thickness and radius under loads of any type. The general equations of arch analysis are first written, from which the deflections and stresses in the arch may be obtained. These equations are then modified to include the concept of a "trial crown thrust," this concept making it possible to obtain arch stresses and deflections with all necessary accuracy when the greater part of the computations are performed graphically. The graphical constructions used in evaluating the equations are developed, the procedure is outlined in detail, and an illustrative example is given.

INTRODUCTION

In 1936 the Design Division of The Metropolitan Water District of Southern California undertook the design of the Gene Wash and Copper Basin Dams,[3] arch structures 156 and 210 ft high which form reservoirs near the easterly end of the Colorado River Aqueduct. In analyzing the designs for these dams, a system of trial load analysis was developed and successfully applied, following the principles presented by C. H. Howell, M. Am. Soc. C. E., and the late Mr. A. C. Jaquith.[4] A most important part of this system was the analysis of the arches. Disregarding the broader aspects of the analysis of arch dams, the details of the method of analyzing arches, as applied to this problem, are herein outlined.

NOTE.—Published in January, 1939, *Proceedings*.

Although, to date, the procedure presented has been used only for dam arches, it is equally applicable to arches of other types. It covers any fixed-end arch, symmetrical or otherwise, under any loading or temperature change. Deformations due to moment, thrust, shear, and uniform temperature change are included. Complications such as foundation deformation, interior arch sections, moment loads, and non-uniform temperature change, may be introduced.

The general theory of arch analysis will be reviewed briefly. The usual assumptions as to homogeneity of material in the arch and the application of Hooke's law are made. The arch is considered as cut at some point known as the crown. The effect of either half of the arch upon the other is then replaced by three unknown forces acting at the crown, a moment, M_c, and two direct forces, H and V. These three forces are applied to both halves of the arch, but in opposite directions, and each half of the arch is considered as a cantilever acted upon by its share of the external load, the temperature change, and the unknown crown forces. Equations are then written which give the three cantilever deflections at the crown (rotation, β_c, and translations, Δ_x and Δ_y). As the crown deflections are the same for each half of the arch, corresponding expressions for the two halves are equated, giving three formulas that may be solved simultaneously for the values of the crown forces. With the crown forces determined, each half of the arch is analyzed as a cantilever under a known system of loads.

The foregoing general approach to arch analysis has been presented in detail elsewhere[3] and in the following explanation it is assumed to be familiar to the reader. The equations for the crown deflections of an arch are given without derivation. Starting from this point, necessary changes are made in the equations, and the graphical construction used in this method of arch analysis is developed.

Notation.—The symbols used in this paper are defined where they first appear and are assembled for reference in the Appendix. The sign conventions adopted for the paper are either given in the definitions or illustrated by Fig. 1.

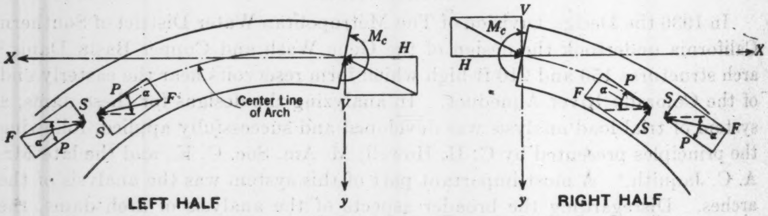

FIG. 1.—SIGN CONVENTIONS FOR ARCH ANALYSIS; POSITIVE QUANTITIES ILLUSTRATED

EQUATIONS

General equations for the crown deformations of an arch, including the effects of moment, thrust, shear, and temperature strain, were given by George R. Rich,[5] M. Am. Soc. C. E., in 1929. The crown deformations for the left half of the arch are:

---

[5] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1230.

Rotation at the crown:

$$\beta_c = +\sum_l \frac{M_e\,s}{E\,I} + \sum_l \frac{V\,x\,s}{E\,I} + \sum_l \frac{H\,y\,s}{E\,I} + \sum_l \frac{M_c\,s}{E\,I} \quad \ldots\ldots\ldots (1)$$

vertical deflection at the crown (positive upward):

$$\begin{aligned}\Delta_y = &+\sum_l \frac{M_e\,x\,s}{E\,I} + \sum_l \frac{V\,x^2\,s}{E\,I} + \sum_l \frac{H\,x\,y\,s}{E\,I} + \sum_l \frac{M_c\,x\,s}{E\,I} \\ &-\sum_l \frac{P_e\,s\sin\alpha}{E\,t} + \sum_l \frac{V\,s\sin^2\alpha}{E\,t} - \sum_l \frac{H\,s\sin\alpha\cos\alpha}{E\,t} \\ &+ y_{al}\,\epsilon\,T + n\sum_l \frac{S_e\,s\cos\alpha}{E\,t} + n\sum_l \frac{V\,s\cos^2\alpha}{E\,t} + n\sum_l \frac{H\,s\sin\alpha\cos\alpha}{E\,t} \quad \ldots (2)\end{aligned}$$

and, horizontal deflection at the crown (positive leftward):

$$\begin{aligned}\Delta_x = &+\sum_l \frac{M_e\,y\,s}{E\,I} + \sum_l \frac{V\,x\,y\,s}{E\,I} + \sum_l \frac{H\,y^2\,s}{E\,I} + \sum_l \frac{M_c\,y\,s}{E\,I} \\ &+\sum_l \frac{P_e\,s\cos\alpha}{E\,t} - \sum_l \frac{V\,s\sin\alpha\cos\alpha}{E\,t} + \sum_l \frac{H\,s\cos^2\alpha}{E\,t} \\ &- x_{al}\,\epsilon\,T + n\sum_l \frac{S_e\,s\sin\alpha}{E\,t} + n\sum_l \frac{V\,s\sin\alpha\cos\alpha}{E\,t} + n\sum_l \frac{H\,s\sin^2\alpha}{E\,t} \quad \ldots (3)\end{aligned}$$

in which: β_c = the slope or rotation of the arch center line, at the crown (positive counter-clockwise); l = a subscript that refers to the left half of the arch; M_e = moment in the arch, taken about the center line, due to external loads; x and y = rectangular co-ordinates with their origin at the crown center line; s = length of a voussoir along the center line; E = modulus of elasticity in direct stress; I = moment of inertia of a radial section of arch; V = vertical force at the crown; H = horizontal force at the crown; M_c = moment in the arch at the crown; P_e = thrust in the arch parallel to the center line, due to external loads; α = angle between the X-axis and the center line of the arch; t = thickness of the arch, normal to the center line; x_a and y_a = values of x and y, respectively, for the abutment; T = temperature change (rise positive); S_e = shearing force due to external loads only; n = ratio of E to effective modulus in shear $\left(\text{that is, } \frac{E}{\frac{5}{6}E_s}\right)$; and, ϵ = thermal coefficient of expansion.

Similar equations may be written for the right side of the arch, with appropriate changes in signs.

It is convenient to write Equations (1), (2), and (3) for the left side of the arch in the following form:

$$E\,\beta_c = +A_{1l}\,M_c + B_{1l}\,H + C_{1l}\,V + D_{1l} \quad \ldots\ldots\ldots\ldots (4a)$$

$$E\,\Delta_y = +C_{1l}\,M_c + B_{2l}\,H + C_{2l}\,V + D_{2l} \quad \ldots\ldots\ldots\ldots (4b)$$

and,

$$E\,\Delta_x = +B_{1l}\,M_c + B_{3l}\,H + B_{2l}\,V + D_{3l} \quad \ldots\ldots\ldots\ldots (4c)$$

For the right side of the arch the equations are similar but with negative signs prefixed to the left sides of the equations.

TABLE. 1.—VALUES OF THE COEFFICIENTS A, B, C, D, AND G

Coefficient	Quantity No.	Definition	SIGNS, AT RIGHT AND LEFT HALVES	
			Left	Right
A_1	1	$\Sigma \frac{s}{I}$	+	+

	16	$y_a\,\epsilon\,T\,E$	+	−
D_3	17	$\Sigma \frac{M_e\,y\,s}{I}$	+	+
	18	$\Sigma \frac{P_e\,s \cos\alpha}{t}$	+	+
	19	$n\,\Sigma \frac{S_e\,s \sin\alpha}{t}$	+	+
	20	$x_a\,\epsilon\,T\,E$	−	−
G_1	21	$\Sigma \frac{M_t\,s}{I}$	+	+
G_2	22	$\Sigma \frac{M_t\,x\,s}{I}$	+	−
	23	$\Sigma \left(\frac{P_t\,s \sin\alpha}{t} - n \frac{S_t\,s \cos\alpha}{t} \right)$	−	+
	24	$y_a\,\epsilon\,T\,E$	+	−
G_3	25	$n\,\Sigma \frac{M_t\,y\,s}{I}$	+	+
	26	$\Sigma \left(\frac{P_t\,s \cos\alpha}{t} + n \frac{S_t\,s \sin\alpha}{t} \right)$	+	+
	27	$x_a\,\epsilon\,T\,E$	−	−

Upon substituting $(1 - \sin^2 \alpha)$ for $\cos^2 \alpha$, and combining terms, the values of the coefficients, A, B, C, D, etc., are brought into the forms given in Table 1. As an example of the interpretation of this table, the B_2-coefficients are written out in the usual algebraic form:

$$B_{2l} = + \sum \frac{x\, y\, s}{I} + (n - 1) \sum \frac{s \sin \alpha \cos \alpha}{t} \quad \text{..........(5a)}$$

and,

$$B_{2r} = - \sum \frac{x\, y\, s}{I} - (n - 1) \sum \frac{s \sin \alpha \cos \alpha}{t} \quad \text{..........(5b)}$$

The corresponding crown deflections for the two sides of the arch as given by Equations (4) are now equated. In the resulting expressions the coefficients for the left and right sides are combined to give new coefficients as follows:

$$A_1 = A_{1l} + A_{1r} \quad \text{......................(6a)}$$

$$B_1 = B_{1l} + B_{1r} \quad \text{......................(6b)}$$

$$C_1 = C_{1l} + C_{1r} \quad \text{......................(6c)}$$

$$D_1 = D_{1l} + D_{1r} \quad \text{......................(6d)}$$

and, similarly, for coefficients with the subscripts, 2 and 3. Using these new coefficients the three formulas resulting from equating the crown deflections are,

$$A_1\, M_c + B_1\, H + C_1\, V + D_1 = 0 \quad \text{..............(7a)}$$

$$C_1\, M_c + B_2\, H + C_2\, V + D_2 = 0 \quad \text{..............(7b)}$$

and,

$$B_1\, M_c + B_3\, H + B_2\, V + D_3 = 0 \quad \text{..............(7c)}$$

When the A, B, C, and D coefficients are determined for any arch, their values may be substituted in Equations (7). Simultaneous solution of these three equations then gives the values of the crown forces, M_c, H, and V.

TRIAL CROWN FORCE

In the system of analysis presented herein, Equations (7) are replaced by another similar set of formulas.

To show the need for this substitution, it will first be assumed that Equations (7) are being used. After the values of the crown forces have been determined from them, each half of the arch is considered as a cantilever acting under a known system of loads. From these loads, the moments, thrusts, and shears in the arch are obtained, and from the latter, in turn, the deflections are computed. It is found that in a comparatively thin arch most of the deflections are moment deflections. Thus, the accuracy with which the moments in the arch are found may largely determine the accuracy with which the deflections are found. The general equation for moment in the left half of an arch is,

$$M_l = M_c + H\, y + V\, x + M_{el} \quad \text{................(8)}$$

For the right half of the arch a similar equation holds, with a minus sign before the term, $V\, x$. With ordinary loads on a thin arch the value of M_{el} at any point will be negative and may be ten or a hundred times as large as the value of M_l. If the external load and the arch are reasonably symmetrical the values of M_c and $V x$ will be small, but the value of $H y$ will be positive and numerically about the same as the value of M_l. Thus, the value of M_l depends upon the difference of two relatively large values, M_{el} and $H y$; and a small percentage error in either of these values will make a large percentage error in M_l. Using graphical procedures it has been found to be impracticable to evaluate these functions with enough accuracy to obtain a satisfactory determination of deflections for an arch.

To avoid this difficulty the concept of the "trial crown force" is introduced. The value of H is considered as divided into two parts,

$$H = H_t + H_c \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

in which H_t is the trial crown force. Its value is chosen at the beginning of an analysis, as close to H as it may be estimated; thereafter it is handled as if it were a part of the external load. Equations (7) may now be solved exactly as previously explained except that the value of H that is determined is not the true horizontal crown thrust but is H_c, that part of the crown thrust that was not included in the trial crown thrust, H_t. To avoid confusion, however, Equations (4), (7), and (8) are rewritten using a notation which includes the use of a trial crown thrust, H_t, as an external load. First Equation (8) becomes,

$$M_l = M_c + H_c y + V x + M_{tl} \ldots\ldots\ldots\ldots\ldots (10)$$

for the left half, and with $(-\,V x)$ for the right half. Symbol M_t is the moment at any point on the center line of the arch, due to the external loads and the trial crown force.

If H_t has been chosen close to the value of H, H_c will be small and M_{tl} will be of the same order as M_l. Thus, the accuracy obtainable with graphical procedure is sufficient to give a satisfactory determination of deflections in an arch, as will be shown subsequently.

Using the notation which includes the trial crown force, H_t, as an external load, Equations (4) become,

$$E\,\beta_c = +\,A_{1l}\,M_c + B_{1l}\,H_c + C_{1l}\,V + G_{1l} \ldots\ldots\ldots (11a)$$

$$E\,\Delta_y = +\,C_{1l}\,M_c + B_{2l}\,H_c + C_{2l}\,V + G_{2l} \ldots\ldots\ldots (11b)$$

and,

$$E\,\Delta_x = +\,B_{1l}\,M_c + B_{3l}\,H_c + B_{2l}\,V + G_{3l} \ldots\ldots\ldots (11c)$$

and, similarly, with minus signs on the left, for the right side of the arch. The G-coefficients are the same as the D-coefficients except that M_e, P_e, and S_e are replaced by M_t, P_t, and S_t, in which P_t and S_t are thrust and shear due to external loads and trial crown force. The G-values are given in Table 1. They may be combined similarly to Equations (6), thus:

$$G_1 = G_{1l} + G_{1r} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

and, similarly, for G_2 and G_3. Using the concepts and notation of Equations (11), Equations (7) become,

$$A_1\,M_c + B_1\,H_c + C_1\,V + G_1 = 0 \ldots\ldots\ldots\ldots (13a)$$

$$C_1\,M_c + B_2\,H_c + C_2\,V + G_2 = 0 \ldots\ldots\ldots\ldots (13b)$$

and,

$$B_1 M_c + B_3 H_c + B_2 V + G_3 = 0 \quad \ldots\ldots\ldots\ldots (13c)$$

Equations (13) are the formulas that are used in determining the values of the crown forces, by a procedure which will be explained subsequently. The trial crown force need not be restricted to H. Under certain conditions the same concept may be applied beneficially to V or to M_c. The procedure is similar to that shown for H. Generally speaking, however, unless the arch shape or the load is very unsymmetrical, the use of a trial force for H is all that is desirable.

DEFLECTION EQUATIONS

With the values of the crown forces, M_c, H_t, and V, known, the deflections in each half of the arch are calculated. The deflections of the arch crown may be determined by substituting the values of the crown forces into Equations (11); but the deflections at other points are also desired. These deflections are determined by means of the following relations: The rotation at any point of the arch is given by,

$$E\,\beta = \sum_a \frac{M\,s}{I} \quad \ldots\ldots\ldots\ldots (14)$$

In any individual voussoir, the displacement of the end farther from the abutment with respect to the nearer end is composed of four parts, as follows:

Displacement due to moment (at right angles to the center line of the arch) is:

$$\Delta_M = \beta\, s \quad \ldots\ldots\ldots\ldots (15a)$$

displacement due to thrust (parallel to the center line of the arch) is:

$$\Delta_P = \frac{P\,s}{E\,t} \quad \ldots\ldots\ldots\ldots (15b)$$

in which P = the thrust parallel to the arch center line; displacement due to shear (at right angles to the center line of the arch) is:

$$\Delta_S = n\,\frac{S\,s}{E\,t} \quad \ldots\ldots\ldots\ldots (15c)$$

in which S = the shearing force normal to the arch center line; and, displacement due to temperature (parallel to the center line of the arch) is:

$$\Delta_T = \epsilon\, T\, s \quad \ldots\ldots\ldots\ldots (15d)$$

The displacement at any point may be expressed as the vector sum of a series of terms such as Equations (15). In a commonly used system of notation, a vector of length, r, in a direction making an angle, θ, with the positive X-axis is denoted by $r\,e^{i\theta}$, and the vector sum of two such vectors is indicated simply by using a plus sign.[6]

---

[6] See, for instance, "Engineer's Manual," by Ralph G. Hudson (1917), pp. 61–62.

In this notation, the deflection at any point on the left side of the arch can be found in magnitude and direction from,

$$E\,\Delta = \sum_{a}\left[E\,\beta\,s\,e^{i(\alpha+0.5\pi)} + \frac{P\,s}{t}\,e^{i(\alpha+\pi)} + n\,\frac{S\,s}{t}\,e^{i(\alpha+0.5\pi)} + \epsilon\,T\,E\,s\,e^{i\alpha}\right]\,.\,.(16)$$

and, similarly, for the right side, with appropriate changes in sign.

FINITE VOUSSOIRS

The terms in Table 1 have been written as summations of finite units. This is necessary as graphical constructions are to be used in the evaluation of the terms. Thus it is that the arch is considered divided into a number of finite lengths called voussoirs, each voussoir having a length, s. Any number of voussoirs may be chosen, but it is found that using from six to eight, of about equal length in each half of the arch, gives satisfactory results. The ends of the voussoirs are referred to as joints and are numbered from the crown to the abutments, left and right.

As finite voussoirs are used it is necessary to determine, in respect to each function, such as M, P, S, t, and I, whether it is to be measured at the joints or at the mid-points of the voussoirs. In this analysis the following convention is used: That part of the load on the arch which lies between the centers of adjacent voussoirs is considered as acting as a concentrated load at the joint. Thus, the thrust and shear are considered constant through the length of a voussoir. The length, s, entering into the $\frac{s}{t}$-terms, or thrust and shear terms, is measured from joint to joint, and the t-values are measured at the centers of the voussoirs. Increments of thrust and shear deflection are thus found from joint to joint.

As the change in moment values is obtained by multiplying the shear values by the length of the voussoir, the moments are found at the joints, and are considered as constant from center to center of adjacent voussoirs. In finding the $\frac{s}{I}$-values entering into the moment deflection terms, the s-values, therefore, are measured between voussoir centers, and the I-values are computed from t-values measured at the joints.

The $\frac{M\,s}{I}$-values, or curvature values, like the M-values, are considered as constant from center to center of voussoirs, giving increments of slope or rotation from center to center. Then rotations are found at the voussoir centers, and are considered as constant from joint to joint. Increments of moment deflections are thus found from joint to joint, just as for the thrust and shear deflections. All deflections, then, are found at the joints.

GRAPHICAL MULTIPLICATION AND INTEGRATION

Several of the functions listed in Table 1 are evaluated by a method of graphical multiplication and integration. An example of this procedure is given in Fig. 2, as taken from Figs. 3 and 4. The values of y and $\frac{s}{I}$ being given for each joint, it is desired to determine the values of $\sum \frac{y\,s}{I}$ and $\sum \frac{y^2\,s}{I}$ for the left half of an arch. On a vertical line called the "y-base" (see Fig. 3(c)), the values of y are laid off to a given scale, each value being measured from the zero point. From an origin on a horizontal line called the "$\sum \frac{s}{I}$-base," values of $\frac{s}{I}$ (Fig. 3(d)) are laid off, successively, to another arbitrary scale. The abscissa of each point thus established then represents the value of $\sum \frac{s}{I}$ taken from the crown to some voussoir center, whose number is given to the point. Vertical lines are drawn through these $\sum \frac{s}{I}$-points, and are called by the same numbers.

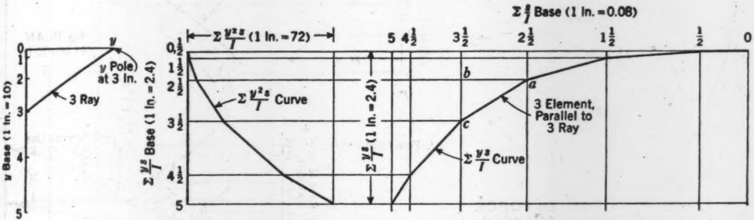

FIG. 2.—GRAPHICAL MULTIPLICATION AND INTEGRATION

A "y-pole" is established at a point an arbitrary horizontal distance ("pole distance") from the zero point of the y-base (Fig. 3(c)). Rays are considered as drawn from the y-pole to each of the points on the y-base. A broken line called the "$\sum \frac{y\,s}{I}$-curve" (Fig. 3(e)), is drawn as follows: Parallel to a ray from the y-pole to Point 1 on the y-base a line is drawn, called the "1 element," beginning at a point on the $\frac{1}{2}$ line of the $\sum \frac{s}{I}$-base and continuing to the $1\frac{1}{2}$ line. Parallel to a ray from the y-pole to the 2 point on the y-base is drawn a "2-element," beginning at the end of the 1-element and continuing to the $2\frac{1}{2}$-line of the $\sum \frac{s}{I}$-base. The procedure is continued to the abutment, the y-value at the abutment being used with the $\frac{s}{I}$-value for the last half voussoir. The projection on a vertical line of the jointed line thus drawn is the value of $\sum \frac{y\,s}{I}$ to a certain scale. The proof is as follows: Consider (Fig. 2) the 3-ray and the 3-element. Then, in the similar triangles (y, 0, 3), and (a, b, c), $\frac{(y,\,0)}{(0,\,3)} = \frac{(a,\,b)}{(b,\,c)}$; whence,

FIG. 4.—ANALYSIS OF RIGHT HALF OF ARCH

$(b, c) = \dfrac{(a, b)\ (0, 3)}{(y, 0)}$. The values of the three factors on the right are: $(y, 0)$ = pole distance (in.); $(0, 3) = \dfrac{y\text{-value of Point 3 (ft)}}{y\text{-scale}\left(\dfrac{\text{ft}}{\text{in.}}\right)}$; and,

$$(a, b) = \frac{\dfrac{s}{I}\text{ of arch length, } 2\tfrac{1}{2} - 3\tfrac{1}{2}\left(\dfrac{1}{\text{ft}^3}\right)}{\dfrac{s}{I}\text{-scale}\left(\dfrac{1}{\text{in-ft}^3}\right)},$$

in which "y-scale $\left(\dfrac{\text{ft}}{\text{in.}}\right)$" denotes the number of feet of y corresponding to 1-in. on the diagram. Substitution gives,

$$(b, c) = \frac{\left[\dfrac{s}{I}\left(\dfrac{1}{\text{ft}^3}\right)\right][y\ (\text{ft})]}{\left[\dfrac{s}{I}\text{-scale}\left(\dfrac{1}{\text{in-ft}^3}\right)\right]\left[y\text{-scale}\left(\dfrac{\text{ft}}{\text{in.}}\right)\right][\text{pole distance (in.)}]} \qquad \text{..(17)}$$

The interpretation of Equation (17) is that the vertical component of an element of the $\sum y \dfrac{s}{I}$-curve represents the product, $y \dfrac{s}{I}$, to a scale which is the continued product of the $\sum \dfrac{s}{I}$-scale, the y-scale, and the pole distance. Then, the vertical component of the entire $\sum \dfrac{y\,s}{I}$-line represents the value of $\sum \dfrac{y\,s}{I}$ to the same scale.

To obtain the value of $\sum \dfrac{y^2\,s}{I}$, a similar procedure is followed. As successive points of the $\sum \dfrac{y\,s}{I}$-curve are established, horizontal lines are drawn through them. These determine points on a vertical line called the $\sum \dfrac{y\,s}{I}$-base. A $\sum \dfrac{y^2\,s}{I}$-curve is drawn so that each element is perpendicular (instead of parallel) to the corresponding ray through the y-pole, and intersects the preceding and succeeding elements on the horizontal lines just mentioned. The horizontal component of the length of the $\sum \dfrac{y^2\,s}{I}$-curve represents the value of $\sum \dfrac{y^2\,s}{I}$ to a certain scale. Proof is analogous to the foregoing for the $\sum \dfrac{y\,s}{I}$-construction.

Other graphical procedures given in this paper are not as general in their use as the foregoing, and will be either self-explanatory or will be explained as their use is described.

METHOD OF ANALYSIS

In starting an analysis the loads on the arch, the temperature change in the arch, and the physical dimensions and characteristics of the arch, are assumed to be known. Furthermore, the factors governing foundation deformations are assumed to be known.

To illustrate the procedure used in this method of arch analysis an example will be given in detail. For simplicity the illustration is confined to an unsymmetrical fixed-end arch without foundation deformations. The loads considered are restricted to direct forces in the plane of the arch, and a uniform temperature change is assumed. Without appreciable error, n is assumed equal to 3. At the end of this explanation, the manner in which other factors may be introduced will be indicated. It should also be noted that, in order to simplify the example, a smaller number of voussoirs are used than is generally desirable.

The arch chosen for this example is a section of the Gene Wash Dam, in California, at Elevation 710, and the loading is approximately that used at one stage of the trial-load analysis of that dam. All the graphical work of arch analysis is done on one large sheet (Figs. 3 and 4). The numerical work is contained in Tables 2 and 3 and in the solutions of the equations in Steps (29) and (30) presented subsequently herein. All quantities pertaining to the structure are given in units of feet and pounds and combinations of those units, exclusively, so that no further notation of dimensions is necessary. In the explanation that follows the graphical constructions referred to as *a*, *b*, *c*, etc., are to be found on Figs. 3 and 4. Steps that are followed separately for the two sides of the arch are described for the left side of the arch only.

PROCEDURE

(1) In Construction (*a*) lay out the arch to a convenient scale and locate the center line. Establish a crown point.

(2) Along the center line of the arch, lay off voussoir lengths starting at the crown. Locate the centers of the voussoirs.

(3) Number the ends of the voussoirs along the center line, starting with 0 at the crown and numbering to the abutment. Assign whole numbers, 1 *l*, 2 *l*, etc., to the joints (ends of voussoirs) and half numbers, ½ *l*, 1½ *l*, etc., to the voussoirs themselves or to their centers. List the numbers in Column (1), Table 2.

(4) Scale the thickness of the arch at the center and ends of each voussoir and list in Column (2), Table 2.

(5) In Column (3), Table 2, list the voussoir lengths as measured along the center line of the arch.

(6) Calculate values of $\frac{s}{t}$ in Column (4), Table 2. Add these values to obtain the value of $\sum \frac{s}{t}$ and list this at the bottom of the column.

(7) Scale the distances along the center line of the arch between the centers of the voussoirs. At the crown and abutment, use the distance from crown or abutment to the center of the adjacent voussoir. List the distances in Column (5), Table 2.

(8) Calculate values of $\frac{1}{I} = \frac{12}{t^3}$ and $\frac{s}{I}$ in Columns (6) and (7), Table 2.

TABLE 3.—COMPUTATION OF COEFFICIENTS; ILLUSTRATIVE EXAMPLE (ϵ = 0.0000056 per Degree Fahrenheit; T = − 10.0° F; E = 432 000 000; $\epsilon T E$ = − 24 200; n = 3)

27	....	+104.5	+87.8	+2 530 000	+2 125 000	G_3 =	−294 000

(9) Starting at the crown, add progressively values of $\frac{s}{I}$ to obtain values of $\sum \frac{s}{I}$ in Column (8), Table 2.

(10) In Construction (*b*), establish a horizontal line, or "*x*-base," and in Construction (*c*), a vertical line, or "*y*-base." Through the ends of the voussoirs on the center line, draw vertical and horizontal lines, known as *x*-lines and *y*-lines. Number the intersections of these lines with the *x*-base and *y*-base to correspond with the numbers of the ends of the voussoirs.

(11) Locate x-poles and y-poles on perpendiculars through the zero points of the x-base and y-base, at distances that will give convenient sizes for the curves described subsequently. Record the pole distances, in inches.

(12) In Construction (*d*), plot a $\sum \frac{s}{I}$-base as follows: From a zero point lay off, horizontally to some convenient scale, values of $\sum \frac{s}{I}$ from Column (8), Table 2. Record the scale and number the points established with the corresponding voussoir numbers. Draw through each point a vertical line.

(13) In Construction (*e*), use the y-pole and y-base to plot a $\sum \frac{y\,s}{I}$-curve on the $\sum \frac{s}{I}$-base, and a $\sum \frac{y^2\,s}{I}$-curve on the $\sum \frac{y\,s}{I}$-base. This procedure is one of graphical multiplication and integration, and has been described previously.

(14) In Construction (*f*), use the x-pole and the x-base to plot $\sum \frac{x\,s}{I}$ on the $\sum \frac{s}{I}$-base, and $\sum \frac{x^2\,s}{I}$ on the $\sum \frac{x\,s}{I}$-base; and in Construction (*g*) plot $\sum \frac{x y s}{I}$ on the $\sum \frac{y\,s}{I}$-base. This procedure is similar to that of Step (13).

(15) In Column (9), Table 2, list the load considered to act at each joint. Take this as the total load actually acting between centers of the voussoirs; except that at the crown, take the load actually applied in the adjacent half-voussoir.

(16) Estimate a trial horizontal crown force, H_t, as by multiplying the average unit load on the arch by the estimated average radius of the thrust line. Apply the same crown thrust to each half of the arch.

(17) In Construction (*h*), draw a force polygon to a convenient scale. Include H_t and the loads of Column (9), Table 2. Start the polygon from a point called the F_t-pole. From this pole plot, horizontally, a vector representing H_t, and from the end of H_t plot, successively, vectors representing in magnitude and direction all the loads on the half-arch, beginning at the crown. Mark the points on this polygon with half-numbers, Point $1\frac{1}{2}$ being between the loads at Joints 1 and 2, etc.

(18) Through the F_t-pole draw a ray, or P_t-line, for each voussoir, in the direction of the thrust, P_t, in the voussoir. Take this direction as parallel to a line through the two center-line points at the ends of the voussoir.

(19) Obtain the average shear, S_t, in each voussoir by scaling the perpendicular distance from its P_t-line to its force polygon point. List these values in Column (10), Table 2. If the diagram is drawn as shown, call the shear, S_t, positive if the P_t-line is below the force polygon point.

(20) Multiply S_t by s of Column (3), Table 2, to obtain, in Column (11), the change in moment between the ends of each voussoir. Sum up from the crown toward the abutment to obtain values of M_t in Column (12).

(21) In Construction (*b*), draw a horizontal reference line intersecting the x-lines. From this line plot, to a convenient scale, values of M_t to form an M_t

versus x-curve. Plot positive values upward. To form an M_t-base, project the points on this curve horizontally on to a vertical line.

(22) Locate an M_t-pole on a perpendicular through the zero point of the M_t-base, at a convenient distance. Record this pole distance, in inches.

(23) Using the M_t-base and M_t-pole, plot: $\sum \frac{M_t\,x\,s}{I}$ on the $\sum \frac{x\,s}{I}$-base (Construction (*i*)); $\sum \frac{M_t\,y\,s}{I}$ on the $\sum \frac{y\,s}{I}$-base (Construction (*j*)); and, $\sum \frac{M_t\,s}{I}$ on the $\sum \frac{s}{I}$-base (Construction (*k*))—all by the method of "graphical multiplication and integration."

(24) Find values of F_t, the resultant force at any point due to external loads and the trial crown force, by scaling, on the force polygon (Construction (*h*)), from the F_t-pole to each numbered point ($\frac{1}{2}$, $1\frac{1}{2}$, etc.). List the values in Column (13), Table 2. Multiply by $\frac{s}{t}$ of Column (4) and list the products, $\frac{F_t\,s}{t}$, in Column (14).

FIG. 6.—CONSTRUCTION FOR FUNCTIONS, $\Sigma\,\frac{s}{t}\sin\alpha\cos\alpha$ and $\Sigma\,\frac{s}{t}\sin^2\alpha$

(25) In Construction (*l*), draw an "F_t-deflection diagram," an element of which is illustrated in Fig. 5. Proceed as follows: To some convenient scale plot the value of $\frac{F_t\,s}{t}$ for the first voussoir in the direction of F_t as taken from the force polygon; that is, from the F_t-pole to the point on the polygon corresponding to the voussoir. Resolve this vector into its $\frac{P_t\,s}{t}$ and $\frac{S_t\,s}{t}$-components, the first parallel, and the second normal, to the direction of the center line of the voussoir, as taken from the corresponding P_t-line on the force polygon. Increase the $\frac{S_t\,s}{t}$-component to n, or three times its length, the increase being away from the $\frac{P_t\,s}{t}$-component. From the end of this increased normal, draw the $\frac{F_t\,s}{t}$-line for the next voussoir in the same manner, and repeat the procedure. Continue to the abutment. The horizontal and vertical distances from the

beginning to the end of this construction give, respectively, the values of Quantities Nos. 26 and 23, Table 1, as required for the coefficients, G_3 and G_2. This may be verified by a consideration of Fig. 5.

(26) To obtain the values of Quantities Nos. 4 and 7, Table 1, make Construction (*m*), an element of which is illustrated in Fig. 6. Proceed as follows: From Column (4), Table 2, take the value of $\frac{s}{t}$ for the first voussoir and plot it as a horizontal line on a convenient scale to the right from the point of origin. From the right end of this $\frac{s}{t}$-line draw a line parallel to the center line of the voussoir, and from the origin end draw a line perpendicular to the center line of the voussoir. Using the intersection of the two lines as the origin, repeat the construction for the next voussoir, and continue to the abutment. Take the vertical and horizontal components of the distance from beginning to end of this construction as the required summations. Proof is evident on inspection of the diagram.

(27) At the top of Table 3 list the values of ϵ, T, E, and the value of the product, $\epsilon\, T\, E$, with the same sign as T.

(28) Having now made all the graphical constructions for evaluating the terms listed in Table 1, determine their values and assemble them into the coefficients of Equations (11) and (13) by filling out Table 3. Fill out all lines of the table except Quantities Nos. 1, 6, 10, 24, and 27, as follows: Determine the scale factors for each function in number of units per inch, and list them in Column (2), Table 3. For the moment terms $\left(\text{which are those containing } \frac{s}{I}\right)$ take the scale factors as the product of the appropriate base scales and pole distances, as explained previously (see heading, "Graphical Multiplication and Integration"). For the other terms, take simply the scale used in the graphical work.

Measure off on Figs. 3 and 4 the values, in inches, of each function there determined and list it in the appropriate line of Columns (3) and (4), in Table 3. Prefix to each value, as measured, its proper sign. If, in Figs. 3 and 4, the positive direction of each term introduced has been taken as shown or specified, and if the relative positions of poles and bases are as shown, determine the signs as follows: Take the sign of any function, except that of Quantity No. 26, Table 3, as plus if its value is measured from the abutment end of the curve up or to the left for the left half of the arch, and up or to the right for the right half of the arch. For the function of Quantity No. 26, take the reverse.

In Columns (5) and (6), Table 3, place the product of the "scale" values and the "measured" values, and in Quantities Nos. 4, 11, and 7, also multiply by the factor, $(n - 1)$, or by 2. Determine the sign of each term by multiplying the sign in the "measured" column by the sign in Table 1.

In Quantity No. 1, Columns (5) and (6), Table 3, place the values of $\sum \frac{s}{I}$ as taken from Column (8), Table 2. In Quantity No. 6, Columns (5) and (6), place the values of $\sum \frac{s}{t}$ as taken from Column (4), Table 2; and in Quantity

No. 10, Columns (5) and (6), place the same values multiplied by n, or by 3. The signs are always positive.

From Construction (*a*) scale the values of x_a and y_a, and list them in Columns (3) and (4) of Quantities Nos. 27 and 24, respectively. Prefix the proper signs. Place the products of these quantities and $\epsilon\, T\, E$ in Columns (5) and (6), Table 3. Prefix the sign determined by multiplying the signs of the two factors and the sign given in Table 1. In Column (8), Table 3, add algebraically the proper terms of Columns (5) and (6) to determine the coefficients of Equations (11) and (13).

(29) Substitute the values of the coefficients just found into Equations (13). Solve the three equations simultaneously for M_c, H_c, and V:

$$\begin{aligned} &+ 1.55\, M_c + 17.60\, H_c + 13\, V - 433\,000 = 0 \\ &+ 13.0\, M_c + 459.0\, H_c + 4\,345\, V - 11\,470\,000 = 0 \\ &+ 17.6\, M_c + 456.1\, H_c + 459\, V - 294\,000 = 0 \end{aligned}$$

The solution is: $M_c = +\,503\,050$; $H_c = -\,22\,277$; and $V = +\,3\,488$.

(30) Substitute the values of the coefficients for the left half of the arch from Table 3 into Equations (11) to obtain the values of the crown deflections: $E\,\beta_c = +\,36\,000$; $E\,\Delta_y = -\,11\,031\,000$; $E\,\Delta_x = -\,325\,000$. The same deflections may be computed for the right half of the arch.

This completes the first part of the arch analysis. The following procedure evaluates the deflections at all points in the arch and determines the arch stresses.

(31) On the y-base (Construction (c)), plot values of $H_c\, y$ to the scale used for M_t in Step (21), as follows: Compute $H_c\, y$ for any point; plot its value horizontally from the corresponding point on the y-base to the scale of M_t; and through this point and the zero point of the y-base draw a straight line. The intercepts between this line and the y-base are the required $H_c\, y$-values at all points.

(32) Construct a curve of values of $(M_c \pm V\,x + H_c\, y)$, *versus* x, with the same scale and the same reference or zero line as the M_t-curve drawn in Step (21), but with reversed sign, as follows: From the reference line measure, vertically, the quantity, M_c, and draw a horizontal line. This is the M_c-line. Through the intersection of the M_c-line with the line, $x = 0$, draw a line with slopes such that intercepts on the x-line between it and the M_c-line give the values of $V\,x$. The procedure is similar to that used in Step (31) for finding $H_c\, y$. From the diagram of Step (31), take off values of $H_c\, y$ with dividers and lay them off along the corresponding x-lines from the line just drawn. Connect the points thus found, forming the desired curve.

In the foregoing procedure some confusion may arise as to the direction in which the constructions are made. As stated previously, the signs of the construction are reversed from that of Step (21). Thus, a positive M_c is plotted down, a positive $V\,x$ is plotted down on the left and up on the right, and a positive $H_c\, y$ is plotted down. By plotting the values of $M_c + H_c\, y \pm V\,x$ to the same scale and from the same reference line as M_t, but in the opposite direction, the intercepts on the x-lines between the two curves give the value,

$M = M_t + M_c + H_c\,y \pm V\,x$ (Equation (10)). The value, M, is positive if measured up from the last constructed curve.

(33) Establish a vertical line as an M-base (Construction (n)). Take off values of M with dividers from the construction of Step (32), and lay them off on the M-base from some reference point or origin, plotting positive values upward. Also, scale off values of M and list them in Column (20), Table 2.

(34) Locate an M-pole on a perpendicular through the origin of the M-base, at a convenient distance. Record this pole distance.

(35) In Construction (o), use the M-pole and M-base, to plot $\sum \frac{M\,s}{I} = E\,\beta$ on the $\sum \frac{s}{I}$-base, using the method of graphical multiplication and integration previously explained. Start the diagram at both abutments and work toward the crown, where it should close. With the sign convention on the M-base as stated and the relative pole positions as shown, the value of $\sum \frac{M\,s}{I}$ or $E\,\beta$ will be positive upward. Determine the scale of $E\,\beta$ from the product of the base scales and pole distance.

(36) Scale the values of $E\,\beta$ at each mid-voussoir point on the diagram just drawn and enter them in Column (15), Table 2. Multiply by values of s from Column (3) and enter the product $E\,\beta\,s$ in Column (16).

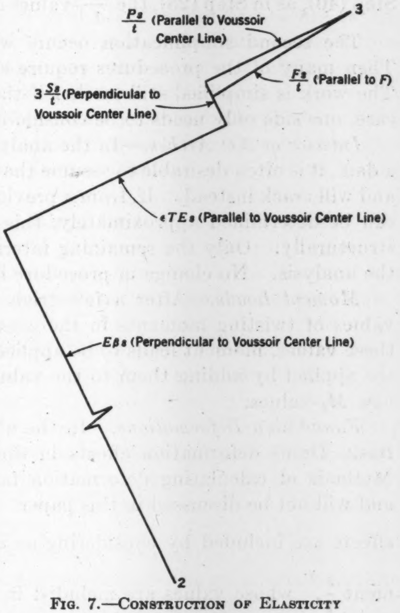
(37) Add, vectorially, the values of H_c and V, determined in Step (29), into the force polygon (Construction (*h*)). To do this, plot, successively, from the F_t-pole, vectors representing in magnitude and direction the values of H_c and V but with reversed sign. That is, plot positive values of H_c horizontally to the right and positive values of V vertically downward on the left-hand polygon, and in the reverse directions on the right-hand polygon. The new pole thus established is the F-pole, and the force polygon from this pole represents the true forces existing in the arch.

(38) Find values of F, the resultant force at any point in the arch, by scaling, on the force polygon, from the F-pole to the numbered points ($\frac{1}{2}$, $1\frac{1}{2}$, etc.) and list them in Column (17), Table 2. Multiply by $\frac{s}{t}$ from Column (4) and enter Product $\frac{F\,s}{t}$ in Column (18).

(39) Multiply s, Column (3), by $\epsilon\,T\,E$ of Step (27) and enter the product, $\epsilon\,T\,E\,s$, in Column (19).

(40) In Construction (p), plot a deflection diagram to a convenient scale, using the vectors indicated in Equation (16). Beginning at some origin plot successively, for each voussoir from abutment to crown, its four increments of deflection. This procedure is illustrated in Fig. 7 for Voussoir $2\frac{1}{2}\,l$. First, plot a vector representing the value, $\frac{F\,s}{t}$, taking the value from Column (18), Table 2, and the direction the same as F, taken from the force polygon. Resolve this vector into its $\frac{P\,s}{t}$ and $\frac{S\,s}{t}$-components parallel and perpendicular to

the voussoir center line, and increase the vector, $\frac{S\,s}{t}$, by three times in the direction away from $\frac{P\,s}{t}$. This procedure is similar to that described in Step (25). From the end of the foregoing construction plot a vector representing, in magnitude and direction, the function, $\epsilon\,T\,E\,s$. This vector is plotted parallel to the arch center line, in the direction away from the abutment if it is positive. Magnitudes are given in Column (19), Table 2. Finally, plot a vector representing, in magnitude and direction, the value of the moment deflection, $E\,\beta\,s$. This vector is plotted perpendicular to the arch center line, a positive value being toward the arch extrados on the left and toward the arch intrados on the right. Magnitudes are given in Column (16), Table 2. Number the points on this diagram the same as the corresponding joint numbers. Plot the crown displacements as computed in Step (30) to check the results of this step.



$\frac{Ps}{t}$ (Parallel to Voussoir Center Line)

FIG. 7.—CONSTRUCTION OF ELASTICITY DEFLECTION DIAGRAM

(41) Calculate stresses. Obtain values of P from the force polygon as follows: For the abutment point take the component in the direction of the arch axis of the distance from the F-pole to the abutment point. For any other joint, obtain P-components for adjacent mid-voussoir points on either side, and interpolate. Obtain M-values from Column (20) and t-values from Column 2, Table 2. The stresses are computed at the desired points with the familiar equations. No example is given.

ADDITIONAL FACTORS

The foregoing simplified example illustrates all the fundamental points of this system of analysis. In order to demonstrate the wide range of applicability of the method, the procedures used in allowing for several other factors will be described briefly. However, before proceeding to these complicating factors, two possible simplifications will be presented. The first concerns the treatment of shear deformations. In thin arches, these deformations are negligible and may very well be omitted. Instead of omitting them entirely, however, it is simpler to assume that the effective shear modulus is equal to E, or that n equals 1. Then, the total deformation due to thrust and shear is always in the direction of the resultant force producing it. In Table 1 the terms with coefficients, $(n - 1)$, drop out. In Step (25), since the $\frac{S_t s}{t}$-components are not to be multiplied by 3, it is unnecessary to resolve the $\frac{F_t s}{t}$-values into components; they are simply plotted, successively, and added vectorially. Since the terms obtained in Step (26) do not appear, this step is omitted. Finally, in Step (40), as in Step (25), the $\frac{F s}{t}$-values are not resolved into components.

The second simplification occurs where the arch shape is symmetrical. Then many of the procedures require solution for one side of the arch only. The work is simplified still further if the loads are also symmetrical. In this case, one side only needs to be considered in all the procedures.

Interior or Net Arches.—In the analysis of a plain concrete arch, such as in a dam, it is often desirable to assume that the concrete is unable to take tension, and will crack instead. If, from a previous analysis, the area subject to tension can be determined approximately, this area can be considered as not acting structurally. Only the remaining interior arch or net section is then used in the analysis. No change in procedure is involved.

Moment Loads.—After a few trials in a trial-load analysis, approximate values of twisting moments in the cantilevers can be determined, and, from these values, moment loads to be applied to arches can be found. These loads are applied by adding them to the values of Column (12), Table 2, to obtain new M_t-values.

Foundation Deformations.—In the analysis of the Gene Wash and Copper Basin Dams deformation effects in the foundation were generally included. Methods of calculating deformation factors have been presented elsewhere[7] and will not be discussed in this paper. However, it may be stated that these effects are included by considering an effective "abutment $\frac{s}{I}$" and an "abutment $\frac{s}{t}$," whose values are included in Columns (7) and (4), respectively, of Table 2, and are handled similarly to the other values in the same columns.

Non-Uniform Temperature.—A dam with its reservoir full of water will have a relatively constant temperature at the up-stream face and may have a quite different temperature at the down-stream face. This results in a temperature gradient, $\frac{dT}{dt}$, in the up-stream-down-stream direction, which may be quite important. To include this effect in the arch analysis the quantity, $\frac{dT}{dt} \epsilon E I$, is computed at each joint and added to M_t of Column (12), Table 2, to obtain a new M_t. These corrected M_t-values are used to determine crown forces and all deflections. In determining stresses the $\frac{dT}{dt} \epsilon E I$-corrections are subtracted from the final M-values.

The foregoing discussion of the inclusion of additional factors into the procedure shows that this method of analysis is readily adaptable to various conditions. In general, it may be stated that any effect that can be included in any type of arch analysis may be included in this procedure. In many details of the procedure, alternative methods are available. Many of these methods have been tried, and some have been found equally as convenient as those adopted, but none was more so.

---

[7] "Ueber die Berechnung der Fundamentdeformation," by Fredrik Vogt, Assoc. M. Am. Soc. C. E., Math. Naturv. Klasse 1925, No. 2.

CONCLUSION

The procedure described herein was used about a hundred times in the course of the analyses of the Gene Wash and Copper Basin Dams in California. When first developed it was used at the same time as an entirely numerical method of computation, and a comparison of the two forms of analysis was possible. The graphical procedure gave accuracy comparable to that of the numerical method, and in both cases some of the work was done by men who followed the mechanical procedure given them, with little or no concern for the principles involved.

Several definite advantages were apparent for the graphical method. In the hands of an experienced operator the graphical procedure has some advantage as to time required. More important, however, is the fact that the graphical procedure presents to the calculator a picture of what has been done. When errors are made they often appear as discontinuities in curves, or as curves of disproportionate size or shape, and, therefore, are discovered much more readily than in the arithmetical method. The picture which the graphical work presents to the calculator also has another value. In an arch which is repeatedly analyzed for varying conditions, all the changes that occur in the component curves of the analysis have a significance to the analyst. For instance, in a case where changes in loads are being made to obtain, in successive analyses, closer approach to desired deflections, he is aided in judging as to whether the changes in assumptions are being chosen properly or what further changes should be made. Thus, whereas a numerical procedure tends to become an endless accumulation of meaningless data, the graphical procedure gives a concise picture of all the component parts of the work.

If different physical characteristics are used for each trial analysis, as when using net sections, a numerical procedure is likely to be very ponderous. The tendency of designers, therefore, has been to avoid the use of net sections or to make simplifying assumptions so as to bring the amount of work within practical limits. As demonstrated in this paper, however, new physical properties of the arch may be accepted, with this method, for each new arch analysis without unduly increasing the work. Thus, this graphical procedure may make practical an exact analysis which by other methods would be too cumbersome.

The concept of the trial crown force is the one important feature that has permitted the development of this method in which satisfactory accuracy is obtained with the extensive use of graphics. It should be noted that this concept would also allow the use of a procedure closely paralleling that presented, in which graphical work would be replaced by arithmetic, and slide-rule accuracy would be sufficient. For a person preferring numerical work to graphical work such a simplification would be of great help.

ACKNOWLEDGMENT

The procedures described in this paper were developed and used in the Design Office of The Metropolitan Water District of Southern California, under the direction of Julian Hinds, M. Am. Soc. C. E., Assistant Chief Engineer. All engineering and construction activities of the District are under the direction of Frank E. Weymouth, Hon. M. Am. Soc. C. E., General Manager and Chief Engineer.

APPENDIX

NOTATION

The following notation conforms essentially with American Standard Symbols for Mechanics, Structural Engineering, and Testing Materials[8] compiled by a Committee of the American Standards Association with Society representation, and approved by the Association in 1932. The sign conventions are either given in the definitions or illustrated by Fig. 1.

A = coefficients in the general arch equations (see Coefficients A, B, C, D, and G, in Table 1);

a = a symbol referring to the abutments; generally used as a subscript;

B = coefficients (see Symbol A);

C = coefficients (see Symbol A);

D = coefficients (see Symbol A);

E = modulus of elasticity in direct stress; E_s = modulus of elasticity in shear;

e = a subscript denoting "due to external loads";

F = a resultant force at any point in an arch; F_t = a resultant force at any point in an arch due to external loads and a trial crown force;

G = coefficients (see Symbol A);

H = a "horizontal" force at the crown; that is, a force parallel to the X-axis; H_c = difference between the estimated and actual values of H at the crown; H_t = the estimated, trial, horizontal crown force;

I = moment of inertia of radial section of an arch;

l = a subscript denoting "the left half of the arch";

M = the moment in an arch at any point, taken about the center line of the arch; M_c = value of M at the crown; M_e = value of M at any point due to external loads; M_t = value of M at any point due to external loads and a trial crown force;

n = ratio of E to effective modulus in shear: $\frac{E}{\frac{5}{6} E_s}$;

P = thrust acting on an arch section, parallel to the center line; P_e = value of P due to external loads; P_t = value of P due to external loads and a trial crown force;

r = length of a vector; as a subscript, r denotes "the right half of the arch";

---

[8] A. S. A.-Z 10A-1932.

S = a shearing force in a plane normal to the center line; S_e = value of S due to external loads only; S_t = value of S due to external loads and a trial crown force;

s = length of a voussoir, measured along the center line;

T = temperature change (rise positive);

t = thickness of the arch, normal to the center line; as a subscript, t denotes "due to external loads and a trial crown force";

V = "vertical" force at the crown; that is, a force parallel to the Y-axis;

x = a distance measured parallel to the X-axis, beginning at the crown center line; the X-axis is called "horizontal" and is approximately parallel to the arch center line at the crown; x_a = values of x for the abutment;

y = a distance measured parallel to the Y-axis, beginning at the crown center line; the Y-axis is called "vertical" and the positive y-direction is called "downward"; y_a = values of y for the abutment;

α = angle between the X-axis and the arch center line;

β = slope, or rotation, of the arch center line (counter-clockwise positive); β_c = the value of β at the crown;

Δ = vector displacement at any point on the arch center line; Δ_x = value of Δ at the crown in the X-direction (positive leftward); Δ_y = value of Δ at the crown in the Y-direction (positive upward);

ϵ = coefficient of thermal expansion;

θ = angular distance; angle between the X-axis and the direction of any vector (sign convention same as for α).

DISCUSSION

I. M. NELIDOV,[9] ASSOC. M. AM. SOC. C. E. (by letter).—The method of graphical analysis given in this paper represents a development over the similar methods in existence, in that it offers, in one complete diagram, the graphical determination not only of forces but also of deformations.

In so far as they refer to Equations (1) to (13) the formulas and coefficients in Table 1 are correct. If a more simple case of a circular arch of constant cross-section under uniform load is taken, the same expression for crown thrust is obtained as is given by the late William Cain,[10] M. Am. Soc. C. E. The derivations, being somewhat voluminous, are not given herein. In reference to the finite voussoirs the writer wishes to emphasize that the selection of the center of the voussoir, at one time for one purpose, and of the ends of the voussoir, at another time for another purpose, does not help to mechanize the process, which in other respects the authors succeeded in doing. The primary cause of this selection is the small number of the voussoirs and the desire to maintain accuracy. It might be better to double the number of voussoirs and thus avoid the complicated assumptions of centers and sides.

It is evident that the authors were greatly interested in evolving the graphical multiplication and integration. The subject of graphical operations of mathematical functions has attracted investigators in the past.[11] Various operations can be performed, such as addition and subtraction, multiplication and division, raising to a given power, evaluation of radicals, operations with trigonometric functions, integration, etc. It is commendable that the authors offered a complete explanation of the graphical processes involved in this method.

As to the "trial force," the writer wishes to remark that this is partly a misnomer and that it is not presented with sufficient clarity. It has been known in the theory of arches[12] that all the forces in an elastic arch can be divided into two classes, the first resulting from the rigid arch and the second resulting from its elastic action. The forces then are called "main" or "original," and "secondary." Using the notation of the paper with the subscript t to indicate the original forces, the expressions for any section of the arch are:

$$P = P_t + P_0 \quad \text{(18a)}$$

$$S = S_t + S_0 \quad \text{(18b)}$$

and

$$M = M_t' + M_0 \quad \text{(18c)}$$

in which the subscript 0 refers to the forces caused by the elastic action, and, M_t' is accented in order to distinguish it from M_t as shown subsequently in Equation (21).

For the crown section Equations (18) become:

$$H = H_t + H_0 \tag{19a}$$

$$V = V_t + V_0 \tag{19b}$$

and

$$M_c = M_t' + M_0 \tag{19c}$$

In Equations (18) and (19) P_t, H_t, S_t, V_t, and M_t' are known, being the forces in the rigid arch resulting from the external forces. Thus:

$$P_t = P_e + H_t \cos \alpha \tag{20a}$$

$$S_t = S_e + H_t \sin \alpha \tag{20b}$$

and

$$M_t' = M_e + H_t\, y + V_t\, x \tag{20c}$$

However, the authors defined M_t as:

$$M_t = M_e + H_t\, y + V\, x \tag{21}$$

thus including, in V, both V_t and V_0. For illustration, in applying Equations (18) to (21) to the case of a circular arch with neutral radius r, constant thickness t, half of the central angle α_1, and uniform radial load p:

$$H_t = \frac{p\, 2\, r^2 \sin^2 (0.5\, \alpha_1)}{r\, (1 - \cos\, (0.5\, \alpha_1))} = p\, r \tag{22a}$$

$$V_t = 0 \tag{22b}$$

$$P_t = 2\, p\, r \sin^2 (0.5\, \alpha) + p\, r \cos \alpha = p\, r \tag{22c}$$

$$S_t = 2\, p\, r \sin\, (0.5\, \alpha) \cos\, (0.5\, \alpha) - p\, r \sin \alpha = 0 \tag{22d}$$

and,

$$M_t' = -\, 2\, p\, r^2 \sin^2 (0.5\, \alpha) + p\, r^2\, (1 - \cos \alpha) = 0 \tag{22e}$$

In other words, the forces with the subscript t are always known because they are obtained from ordinary statics and no "trials" are needed.

In the case of irregular loading and of the arch, Equations (22) may be obtained graphically from the force diagrams of statics. Referring to the method of obtaining the moment M_t by a summation of the values of shears, as shown in Table 2, Columns (11) and (12), it may be noted that the moments M_t' may be obtained directly by graphics, by constructing a force polygon and an equilibrium polygon for the forces acting and superimposing the latter on the neutral line of the arch.

In conclusion, what interests the writer is the statement by the authors that, to include the effect of the non-uniform temperature, one must add to M_t, due to the external forces, the expression $\frac{dT}{dt}\, \epsilon\, E\, I$. The writer suggests that the authors verify it by applying their formulas in Table 1 to the simple case of a circular arch of neutral radius r, uniform thickness t, half the central angle α_1, and finding a total crown thrust H due to this change of temperature. The expression for H is as follows:[13]

$$H = \left[\Delta x - \theta\, r \left(1 - \frac{\sin \alpha_1}{\alpha_1} \right) \right] \frac{2\, E\, I}{D\, r^3} \tag{23}$$

---

[13] *Transactions*, Am. Soc. C. E., Vol. 90 (1927), pp. 492 and 558.

in which the horizontal displacement of the crown section, due to the effect of non-uniform temperature, is

$$\Delta x = r^2 \epsilon \frac{dT}{dt} (\alpha_1 - \sin \alpha_1) + r \epsilon \left(t_i + \frac{t}{2} \frac{dT}{dt} \right) \sin \alpha_1 \ldots\ldots (24a)$$

The rotation of the crown due to the same effect is

$$\theta = \frac{dT}{dt} r \epsilon \alpha_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24b)$$

Coefficient D is

$$D = \left(1 + \frac{I}{t\, r^2} \right) \left(\alpha_1 + \frac{\sin 2\, \alpha_1}{2} \right) - \frac{2 \sin^2 \alpha_1}{\alpha_1} + n \frac{I}{t\, r^2} \left(\alpha_1 - \frac{\sin 2\, \alpha_1}{2} \right) \ldots\ldots\ldots\ldots\ldots\ldots (24c)$$

and, t_i is the temperature at the intrados, in degrees Fahrenheit.

CARL H. HEILBRON, JR.,[14] ASSOC. M. AM. SOC. C. E., AND WILLIAM H. SAYLOR,[15] JUN. AM. SOC. C. E. (by letter).—The comments of Mr. Nelidov indicate that, in several instances, the writers have failed to offer sufficiently clear explanations. It is hoped that the questions raised will be answered satisfactorily herein.

The writers cannot agree with the suggestion that the convention whereby the centers of voussoirs and ends of voussoirs are used alternately "does not help to mechanize the process." In any method wherein all functions are determined at a single set of points it is necessary to average values at adjacent points in every step where integration is to be performed, and it is only by means of a convention such as that adopted that this averaging is avoided. Although the assumptions sound "complicated" when described, any one using them will realize that they result in the simplest possible set of operations.

In this connection Mr. Nelidov suggests the use of a larger number of voussoirs. It may be well to reiterate that in their example the writers, for simplicity, used a smaller number of voussoirs than they would recommend generally.

Mr. Nelidov identifies the "trial" forces with a similar set of forces which he calls "main" or "original." The latter, he says, are "known," meaning, it is presumed, that they can be obtained by processes not involving trial. Using his concept of "original" forces he arrives at a value of M_t' as (see Equation 20(c)) $M_t' = M_e + H_t\, y + V_t\, x$. He then mistakenly states that the writers define M_t (see Equation (21)) as $M_t = M_e + H_t\, y + V\, x$. Actually, the writers define M_t as

$$M_t = M_e + H_t\, y \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

Thus, M_t is identical with M_t' except that V_t is taken as zero. That it is possible to let V_t be zero is due to the fact that the "trial" forces used by the writers are arbitrary values which are used as an aid in improving the accuracy of subsequent calculations, whereas the "original" forces considered by Mr. Nelidov are actual "known" forces which must be calculated. The advantage of the writers' concept of these forces is that they need not be calculated exactly but may be chosen arbitrarily as best suits the needs of the problem. In the case of V_t, it has been found practical to choose a value of zero so that this quantity is eliminated from the procedure.

[15] Asst. Engr., U. S. Engr. Office, Los Angeles, Calif.

Mr. Nelidov's question in regard to the effects of non-uniform temperature change is due, perhaps, to the writers' failure to explain that, in addition to taking the temperature gradient into account, of course, the average change of temperature must be used just as if the change were uniform.

The writers appreciate the fact that Mr. Nelidov brought these points to their attention.

TYPICAL QUANTITATIVE ANALYSIS AS APPLIED TO LAKE SUPERIOR

By C. R. Pettis,[1] M. Am. Soc. C. E.

Synopsis

A method of making a quantitative analysis of the hydrology of the Great Lakes, as illustrated by a detailed study of the hydrology of Lake Superior, is presented in this paper. Certain deductions are made, based on evidence from available data. By means of these deductions, values are obtained for the evaporation from the lake surface. Knowing the evaporation, the underground flow to the lake and the land losses can be computed.

The validity of the method has been checked by evaporation experiments which are described in the companion paper of this Symposium.

The conclusion reached is that the evaporation and the underground flow are greater, and the land losses are less, than the values that have been generally accepted.

Introduction

The hydrology of the Great Lakes has been the subject of several studies: Thomas Russell, of the United States Lake Survey (1906); the late John R. Freeman, Past-President and Hon. M. Am. Soc. C. E. (1926); Robert E. Horton, M. Am. Soc. C. E., and the late Carl E. Grunsky, Past-President, Am. Soc. C. E. (1927); and John F. Hayford and J. A. Folse (1930). Most of them assumed a value for evaporation determined from ordinary land pans; Mr. Freeman assumed that the underground flow to the lake was zero; all of their results differed considerably from those obtained by the present analysis.

A quantitative analysis of the hydrology of Lake Superior must account for the disposal of all the water that enters the main body of the lake, for such periods of time as may be considered. In any given period of time, the total quantity of water that enters the lake, as precipitation on the surface of the lake, river flow and underground flow, will be equal to the evaporation from the lake surface plus the flow through St. Marys River, plus the change in storage, as indicated by lake levels in the same period of time. If the river flow to the lake is known, and the underground flow to the lake can be determined, the tributary land drainage basin can be included in the analysis by using the relationship: Over a period of several years, the rainfall on the land basin is equal to the river flow to the lake, plus the underground flow to the lake, plus the land losses. The term "land losses" includes all land precipitation that does not reach the lake; presumably the land losses consist primarily of land evaporation and transpiration, or other vegetative losses.

ANALYSIS

Formulas.—The following formulas apply to any given period of time:

$$P + R + U = O + S + E \quad \text{.................. (1)}$$

and

$$B = R + U + L \quad \text{........................ (2)}$$

All of the terms in the equations represent volumes of water in the period of time under consideration. They are defined as follows:

P = the rainfall on the surface of the lake, and becomes an immediate addition to the body of water in the lake as soon as it falls. It is assumed that the depth in inches of rainfall on the lake is the same as the depth of rainfall on the land; it was decided that this assumption would give better results in this analysis, because the evidence of a slight difference between P and B is conflicting.

B = the rainfall on the tributary land area. This value was computed from records of 59 stations of the United States Weather Bureau in the area, by taking a weighted average for the sections into which the area was divided.

R = the run-off into the lake from the surface streams as determined from stream-flow records of the United States Geological Survey and other sources, using a method of weighted averages, based on a personal reconnaissance of the area, 49% of which is covered by stream-flow records. The value of R, as a whole, is considered fairly accurate.

U = the net underground flow into the lake, which is not known, and is to be determined.

O = the outflow from the St. Marys River, which is based on careful records kept by the U. S. Engineer Department.

S = the change in storage in the lake, as indicated by gage records, being plus for a rising lake and minus for a falling lake. The gage records are kept by the United States Lake Survey.

E = the net evaporation from the surface of the lake, and is considered in the usual sense of evaporation minus condensation.

L = the difference between the rainfall B and the surface and underground flow into the lake $(R + U)$, for the period under consideration, as given by a transposition of Equation (2).

The period of time used in most of this analysis is one calendar month. Symbols P, R, U, O, S, and E all denote quantities of water that enter or leave the main body of the lake during the month in question. Symbol B is the precipitation on the land area for the same month. In winter much of the precipitation remains on the surface of the ground and does not enter the lake, either as surface flow or underground flow, until the spring thaw. Throughout the year, the land precipitation, B, is subject to a delay before entering the lake, due to both surface and underground storage effects. For this reason, the value of L for any particular month, as obtained by Equation (2), will not represent the land losses (evaporation and transpiration) which pertain to the precipitation of that particular month, the land losses being that portion of the precipitation that does not ultimately enter the lake. Over a number of years, the values of L for the period will represent the land rainfall that does not reach the lake; that is, the land losses, primarily land evaporation and transpiration.

There are two equations and three unknowns, E, U, and L. A rigid solution is impossible; but by making certain assumptions in accord with the present knowledge of the subject (and which, in most cases, seem to be the only reasonable assumptions possible, in view of the evidence) it is possible to arrive at an approximate solution. If one unknown is determined approximately, a rigid solution is possible for the other two unknowns, although the results necessarily cannot be more accurate than the approximate determination of the first unknown.

As far as is known, none of the lakes freezes over entirely in the winter. "Open-water" evaporation refers to the rate of evaporation from the part of the lake that is not covered by ice. The actual evaporation from a lake in the winter will be less than the "open-water" evaporation by an amount that depends on the extent of ice that is formed.

Since January, 1937, evaporation stations have been maintained by the Lake Survey at Detroit, Mich., Kewaunee, Wis., Duluth, Minn., and Buffalo, N. Y. An effort is made to keep the water temperature the same as the temperature of the water in the open lake, which makes them different from ordinary land-pan experiments.

Results reported by Mr. Hickman in this Symposium are based fundamentally on the evaporation experiments. In this paper, a mathematical analysis is made of data which is entirely different from that used by Mr. Hickman, and monthly values of the evaporation on Lake Superior are obtained. The results of the two independent solutions check rather closely; the results obtained by investigators who neglected underground flow do not check with the evaporation experiments. When the evaporation has been determined, by any method, the values of U and L can be determined mathematically from Equations (1) and (2). The analysis and solution given in this paper were made before the evaporation experiments were begun. It is evident from Fig. 1 that the remainder of this paper, with slight modifications, might be considered to be a solution and discussion based on the evaporation experiments.

From the data and Equations (1) and (2), monthly values of $(E - U)$, $(E + L)$, and $(U + L)$ can be obtained which will be as accurate as the data upon which they are based.

As a matter of convenience, in all computations, the water that will cover the land area tributary to Lake Superior to a depth of 1 in., will be used as a unit of volume. Unless otherwise indicated, all data will be given in the same unit. The land area of Lake Superior is 49 078 sq miles. One unit, or 1.0 in. of water on this area, will represent a certain definite quantity, which is practically 114 billion cu ft. The water area of Lake Superior is 31 817 sq miles. The ratio of land area to water area is 1.54. If a 1-in. depth of water on the land were placed in the lake, the lake level would be raised 1.54 in. Inches of depth on the land can be converted to inches of depth on the lake by multiplying by 1.54; and, conversely, inches of depth on the lake can be converted to inches of depth on the land by dividing by 1.54.

In this analysis, the following assumptions are made:

(*a*) It is assumed that the net underground flow into the lake, *U*, is always positive; that is, there will be no monthly period in which there is a net flow of underground water away from the lake. This assumption is definitely indicated by the analysis of curves in this study. The flow of underground water even in the winter has been indicated by Mr. Horton who states:[2] "In case of sandy soils with low field moisture capacity, infiltration takes place at a relatively high rate even when the ground is frozen." Messrs. H. K. Burton

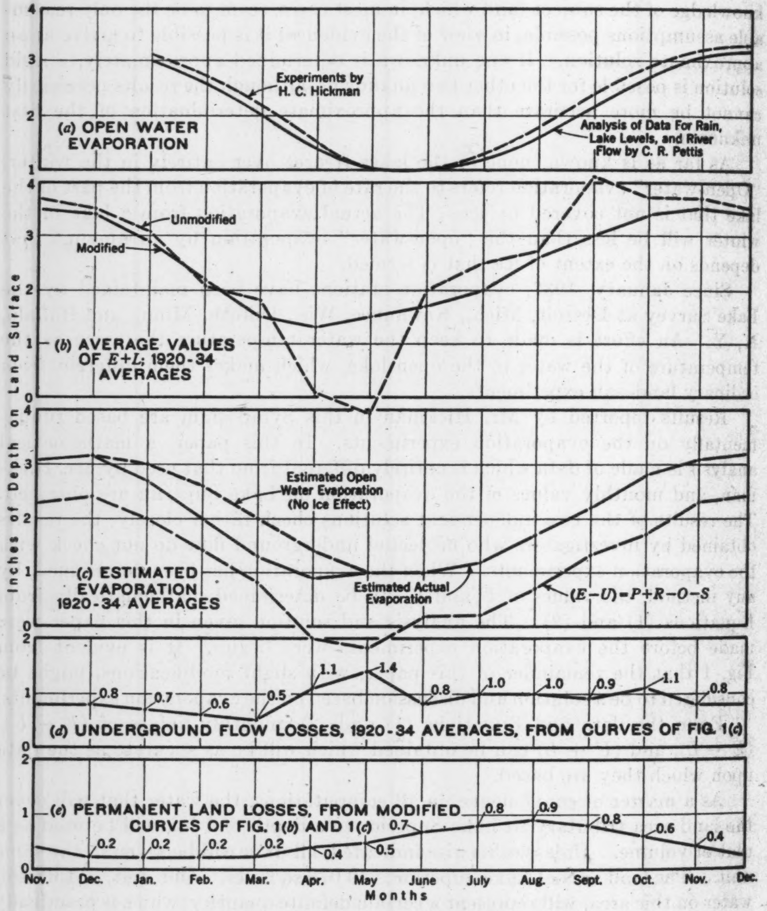

FIG. 1.—HYDROLOGICAL DATA APPLYING TO LAKE SUPERIOR

and J. Cecil Alter state:[3] "The mountain snow-layer melts continually from the bottom, the moisture leaching steadily into the soil."

---

[2] National Research Council Report, 1936, p. 351.

(*b*) It is assumed that the normal open-water evaporation curve for monthly periods will be approximately a sine curve with a periodicity of one year. The curves for air and water temperatures, relative humidity and wind, which are the factors that are supposed to affect evaporation, are approximate sine curves with periodicities of one year. There is some variation from normal in the evaporation for particular months; but, in general, the variation in evaporation from the normal for a particular month is not large. According to H. K. Barrows,[4] M. Am. Soc. C. E., for any given month there is, in general, a greater range in the rate of precipitation than in the rate of evaporation. For that reason less time is required to obtain data of average monthly evaporation sufficiently accurate for use in storage estimates. Other engineers have noted the same condition.

(*c*) The $(E + L)$-curve in Fig. 1(*b*), with obvious modifications, is approximately a sine curve. The curve representing the permanent land losses, when distributed over the months in which the losses occur, should be something like a sine curve; the numerical variations in the permanent (distributed) L-curve are probably less than the variations in any of the other curves.

If the $(E - U)$-curve is plotted by months (see Fig. 2, with Tables 1 and 2), and compared with the rainfall B-curve, it is apparent at once that, in practically every case when the weather is not freezing, a high value of rainfall in one month will be followed by a low value $(E - U)$ in the following month, or sometimes in the second month. This is true for each of the Great Lakes. This relation between B and $(E - U)$ must be accounted for by one of two hypotheses:

(1) The high rainfall in one month causes a radical change in the evaporation for the following month. This assumption is directly contrary to present theories on the subject of evaporation; it is inconsistent with the previous assumption in regard to the regularity of evaporation by monthly periods; and, therefore, this assumption is rejected as being untrue.

(2) High rainfall in one month will be followed by an increase in underground flow which will be most noticeable in the lake in the following month or, say, five weeks later. There is nothing in this assumption contrary to the present knowledge of the subject; it seems reasonable and, therefore, it is adopted for the purpose of this analysis. It may be noted that a high rainfall in the summer will have a greater effect on the underground flow in the next month than the same rainfall in the late fall or winter, which is consistent with the present engineering opinion that underground water flows more freely when the temperatures are warm than when the temperatures are cold (see Table 1).

There is a considerable flow, R, from the surface streams through the winter; November, 0.9 in.; December, 0.7 in.; January, 0.6 in.; and February, 0.5 in. Since the ground in the Superior basin is ordinarily covered with snow during these months, it is assumed that most of this winter flow comes from underground sources. The surface streams can tap only the portion of the underground water that is above certain levels; the underground water below these levels can reach the lake only through underground channels.

---

[3] National Research Council Report, 1936, p. 534.

[4] "Water Power Engineering," by H. K. Barrows, p. 83.

The winter underground flow is deduced by the following analysis: The 6-yr period 1920–1925 was a period of relatively small annual rainfall (average 26.6 in.); and, the 6-yr period 1926–1931 had a greater annual rainfall (average 29.8 in.). The average annual temperature for the two periods varied by less than 0.5° F. If the winter evaporation, December to March, for the two periods is assumed to average the same, the values of $(E - U)$ indicate that the underground flow from December to March for the second period was greater than that for the first period by 0.9 in.

TABLE 2.—Hydrological Data; Lake Superior, Corresponding to Fig. 2.

Description	1921	1924	1930
Net Evaporation, *E*, from the Surface of the Lake:			
November to October, inclusive..................	25.6	23.8	22.1
Run-off, *R*, into the Lake from Surface Streams:			
January of following year..................	0.5	0.5	0.3
February of following year..................	0.5	0.5	0.3
March to February, inclusive..................	9.4	8.2	11.3
Net Underground Flow, *U*, into the Lake:			
January of following year..................	0.7	0.6	0.5
February of following year..................	0.6	0.6	0.5
March to February, inclusive..................	11.8	11.4	9.2
Rainfall, *B*, on Tributary Land Surface:			
November to October, inclusive..................	27.3	25.5	26.1
$R + U$: March to February, inclusive..................	21.2	19.6	20.5
$L = B - (R + U)$: From two items above..................	6.1	5.9	5.6

The rainfall in August, September, and October is a major (but not the sole) factor affecting winter underground flow. From Equation (2), the rainfall available for underground flow is $(B - R - L)$. Taking an average value of L for the given months from Fig. 1(*d*), and using known data, $(B - R - L)$ August to October, for the first period, was 3.4 in., and for the second period, 4.8 in.; the average value was 4.1 in. for both periods combined; and, the difference between the low period and high period was 1.4 in. Assuming that the difference in available rainfall (1.4 in.) is to the difference in winter underground flow (0.9 in.) as the average available rainfall (4.1 in.) is to the average underground flow, then the average underground flow, December to March, is 2.6 in. This was distributed to months as follows: December, 0.8; January, 0.7; February, 0.6; and March, 0.5.

The average monthly values of $(E + L)$ for the 15-yr period, as computed by the formula:

$$E + L = P + B - O - S \dots\dots\dots\dots\dots\dots (3)$$

are shown by the curve in Fig. 1(*b*). For any period long enough to equalize the underground-storage and lake-storage effects, $(E + L)$ will represent the quantity of water that falls on the total area and which has not passed out of the area through St. Marys River.

In the $(E + L)$-curve shown in Fig. 1(*b*), if more water than usual goes into underground (or snow) storage in any particular month, then L for that month —and also $(E + L)$—will contain not only the permanent land loss for that month, but also a temporary loss, which represents water that has gone into storage, and which will decrease the formula values of (E + L) for the later months in which it comes out of storage. It is evident that certain adjustments may be made in the $(E + L)$-curve to obtain a modified $(E + L)$-curve which will represent the values of $(E + L)$ with land losses distributed to the months in which they actually occur. It will be noted that there is a considerable sag in the unmodified $(E + L)$-curve in April and May (see Fig. 1(*b*)). This sag is due to the fact that, in these months, considerable water that had fallen during the winter months, in the form of snow, becomes available for surface flow and underground flow, causing a negative value of L.

The years 1924 and 1931 had the smallest winter precipitation of any years in the 15-yr period under study. The April value of $(E + L)$ for 1924 was 1.1, and the May value of $(E + L)$ for 1931 was 1.4. These values are only slightly less than those adopted for the modified $(E + L)$-curve for these two months. In comparing the $(E + L)$-curve and the modified $(E + L)$-curve, it will be noted that 3.0 in. is gained in the spring thaw. This represents the water that has gone into storage in the preceding months, and which comes out of storage at the time of the thaw. The difference between the $(E + L)$-curve and the modified $(E + L)$-curve (Fig. 1(*b*)) is caused by the varying effects of storage on the values of L.

If the modified $(E + L)$-curve is compared with a sine curve, it will be noted that there is a slight sag in the winter months, ending about May. This is caused by a certain area of ice forming near the shores of the lake in the winter, which reduces the evaporation. Lake Superior very seldom, if ever, freezes over entirely. It is doubtful if as much as half of the lake has frozen over during the period 1920–1934.

Before an attempt is made to analyze the curves for individual years, it is desirable to ascertain the approximate shape of the E-curve for an average year. The average monthly values of $(E - U)$ for the 15-yr period are plotted in Fig. 1(c). Since it is assumed that U is positive at all times, all points of the E-curve must lie above the corresponding points of the $(E - U)$-curve; in each case it is by an amount that is equal to the underground flow for the particular month. Previously, herein, average values of U were assumed for December to March. This assumption yields points on the E-curve for December to March, with the maximum point of the E-curve in December. For open-water evaporation, the minimum point of the curve can be assumed to occur about six months from the maximum point, or about June. The evaporation experiments, reported in this Symposium by Mr. Hickman, indicate that the minimum monthly evaporation to be expected on Lake Superior will not be less than 1 in. (land area unit). It will be assumed that the minimum evaporation in May and June is 1.0 in. per month. The open-water evaporation curve can now be obtained by drawing an approximate sine curve between the high points and the low points, and through the other points determined. The actual evaporation curve, or the full-line curve in Fig. 1(c), is obtained for the month of April by considering that a reduction in evaporation, due to ice, continues through this month.

From the E-curve (Fig. 1(c)), the $(E - U)$-curve (Fig. 1(c)), and the modified $(E + L)$-curve (Fig. 1(b)), the average monthly values for U and the permanent distributed values of L can be obtained. The curves for U and L are shown in Fig. 1(d).

The U-curve is higher in the warm months, and lower in the winter. The highest point is in the spring thaw, when the melting snow is added to the rainfall. The curve reflects the higher rainfalls in July and September, by increased flow in August and October.

The L-curve (Fig. 1(d)) may be considered to be caused primarily by land evaporation and transpiration. The shape of the L-curve suggests that the land-evaporation curve is somewhat similar to that of the ordinary pan-evaporation experiment, being higher in the summer, and, that transpiration losses vary with the activity of vegetable growth. Attention is called to the fact that "land evaporation," as the term is used in this paper, means the evaporation proper (water vapor leaving the land surface), minus condensation (water vapor absorbed from air by soil). According to some investigators, the rate of condensation is considerable.

An estimate has been made of the monthly evaporation for each one of the fifteen years in the period 1920–1934; the result of this detailed analysis for three typical years is shown in Fig. 2, with Tables 1 and 2. The methods used in the analysis have been evolved as the result of an extended study.

The average air temperature and relative wind velocities were computed for each month from data supplied by the U. S. Weather Bureau (see Table 1); a decided departure of either one of these factors from normal for any month will generally have a noticeable effect on the evaporation for that month.

Relative humidity was computed for each month; an effort was made to relate the monthly values of relative humidity to the corresponding data for evaporation, but the conclusion was reached that the monthly relative humidity is more the result of the evaporation than it is the cause of evaporation. For this reason, relative humidity was not used in the analysis; which is equivalent to making the assumption that, for the 15-yr period, the values of relative humidity remain normal according to the period of the year considered.

In the analysis, the first step is to plot monthly values of the $(E - U)$-curve; then values of E are assumed for each month, which best comply with the following conditions:

(1) If air temperature is normal for the month, and has not been abnormal for the months immediately preceding, and if the wind is normal for the month, E should be nearly normal for the month, as shown by the E-curve in Fig. 1(*c*).

(2) A sudden lowering of the temperature for one month will tend to cause a higher value of E for this month; this accords with Dalton's law, since water temperature tends to follow the air temperature, but with a considerable lag.

(3) If air temperatures are above normal for a few months (say, three or more), water temperature will probably be above normal, and E will be increased.

(4) In a cold winter, E will tend to decrease, due primarily to a larger area of ice formed on the lake.

(5) A relatively high wind will cause a higher value of E.

(6) The normal winter values of U previously deduced are assumed to apply, except where modification may be indicated by some of the other factors.

(7) The values of E in the spring months should be such as to reflect the spring thaw in the values of U; and, for different years, the values of U in the spring thaw should have some relation to the winter precipitation.

(8) There should be a relation between the precipitation and the values of U. Abnormally high or low values of B, except in the winter, should be followed in general by high or low values of U within a month or two.

(9) In some cases, the conditions will be conflicting; a few minor discrepancies are to be expected, due to slight errors in the data, or to the method of treating relative humidity.

The application of the foregoing principles to three typical years is shown in Fig. 2, with Tables 1 and 2. The climatic data for each month are plotted on the vertical line beneath the given month. In Table 1, the first line of each sub-table is the average (15-yr) air temperature for the corresponding month. The second line gives the average air temperatures for the months in question. The effect of the air temperature is judged by a comparison of the first two lines. The third line gives the wind velocity for each month as compared with the average (15-yr) wind velocity for that month. The fourth line shows by $(E +)$ or $(E -)$ certain months in which the temperature and wind indicate that the evaporation for the particular months will be appreciably above or below normal for those months.

The $(E - U)$-curve is computed by a transposition of Equation (1). The R-curve is drawn from the tabulated values obtained from the Geological

Survey data. The small circles in the figures indicate the normal evaporation for respective months, as previously determined. The E-curve indicates the estimated monthly evaporation, giving consideration to climatic factors, and to the conditions previously enumerated. The value of U for each month, as shown by the U-curve, is determined by taking the distance between the E-curve and the $(E - U)$-curve.

For convenience in making comparisons, the B-curve, for rainfall on the land, is plotted on the same sheet.

Values of E, R, U, $(R + U)$, B, and L, are presented in Table 2, L being computed from a transposition of Equation (2), using different periods for the several factors, in order to reduce the error in land losses, L, due to temporary storage effect. The twelve-month period, November to October, inclusive, was used for B in this formula; and, March to February was used for R and U, for the following reasons: The precipitation (in the form of snow), from November to February, has a much greater effect on R and U in the spring thaw after March than it does on the winter flow of R and U. The winter flow is affected principally by the rainfall in October and the preceding months, so that the rainfall during the period used in the formula for B reaches the lake principally in the period used in the formula for R and U; and the values of L computed by this method are fairly uniform for most years, since the storage effect will be small unless conditions are somewhat abnormal. The correlation between climatic factors and evaporation, and between rainfall and underground flow can be observed in Fig. 2.

The year 1921 was an unusually warm year, and the evaporation was high (25.6 in.). The high evaporation for this year is further substantiated by a correspondingly high value of $(E + L)$, which can be computed from known factors by Equation (3). The winter of 1930 apparently had more ice than either 1921 or 1924. It was the only year of the three with a November-to-March temperature below normal. The year 1921 had the highest winter precipitation, from November to March, and it also had the largest underground flow in the spring thaw in April and May. The curves in Fig. 2 indicate that there is a fairly close correlation between rainfall, B, and the total flow to the lake, $(R + U)$. The distribution of B between R and U, evidently, depends on other factors than those that have been shown.

Next, consider the possibility of errors in the data, and the effect that such errors might have on the values of E, L, and U. For the purposes of this analysis, it is believed that the values of O and S may be accepted as correct, and that minor errors are more probable in the values of P, B, and R. The following statements are believed to represent the principal effects of possible errors:

From Equation (1), $(R + U) = O + S + E - P$. If the values on the right are assumed to be correct, an error in R will cause an equal error in the opposite direction in U; and to a considerable extent, errors in R will be compensated by opposite errors in U, without affecting the values of E and L.

From Equation (1), $E = P + (R + U) - O - S$. If O and S are assumed correct, and errors in R are compensated in the determined values of U, an error in P will cause an equal error in the same direction in E.

From Equation (2), $L = B - (R + U)$. If errors in R are compensated in the determined values of U, an error in B will cause an equal error in the same direction in L.

The collection of water in rain gages is subject to wind effects, and the water in most gages is subject to some slight evaporation. It is believed that both B and P may be slightly greater than the Weather Bureau data used, and that the values of E and L may be slightly larger than the determined amounts.

Summary and Acknowledgment

The results of this analysis for Lake Superior are as follows:

Land area		Inches of depth on land area
Normal annual rainfall on land is		28.2
Of which land losses are		5.9
The remainder		22.3
Reaches the lake as:		
Surface run-off	11.6	
Underground flow	10.7	

Lake area		Inches of depth on lake area
Normal annual rainfall on lake is		28.2
Annual surface run-off to lake is		17.9
Annual underground flow to lake is		16.5
Total addition to lake in one year is		62.6
Of which annual evaporation is	35.6	
And outflow from St. Marys River is	27.0	

The writer has received assistance from a number of sources, especially from Messrs. Sherman Moore, H. C. Hickman, Jun. Am. Soc. C. E., L. D. Kirshner, and F. W. Townsend, of the Lake Survey, and Professors C. O. Wisler and W. C. Hoad, Members, Am. Soc. C. E., and E. F. Brater, Jun. Am. Soc. C. E., of the University of Michigan, at Ann Arbor, Mich. The data form a part of a thesis[5] by the writer, entitled "Hydrology of the Great Lakes," presented to the University of Michigan in 1938, in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

EVAPORATION EXPERIMENTS

BY HAROLD C. HICKMAN,[6] JUN. AM. SOC. C. E.

SYNOPSIS

The evaporation experiments reported in this paper were conducted at Duluth, Kewaunee, Detroit, and Buffalo, for the purpose of providing a basis for estimating the evaporation from the water surfaces of the Great Lakes. In order to be applicable to local conditions, an effort was made to keep the temperature of the water in the pans approximately the same as the temperature of the water in the open lakes. Data were secured which cover a greater variety of combinations of air and water temperatures and wind velocities at the evaporation pans, than any known heretofore. In applying these data to the Great Lakes it was assumed that the evaporation from the open lakes, for a given air temperature, water temperature, and wind velocity, would be the same as the observed evaporation from the experimental pans for the same combination of air temperature, water temperature, and wind velocity.

The readings were analyzed and plotted on two charts, from which an estimate of the monthly (or daily) evaporation from the Great Lakes can be made. In these charts it has been assumed that the relative humidity and barometric pressure correspond to the average conditions that existed on the shores of the lakes, at all four stations, during the particular time of the year in which the data were being obtained. The experiments indicate that the effect of the wind on evaporation is fundamentally different from that indicated by the common evaporation formula. The rate of evaporation from open-water surfaces when the air temperature is below freezing has been investigated for the first time.

INTRODUCTION

The physical conditions that affect evaporation on the Great Lakes are quite different from conditions in comparatively shallow lakes. Because of the great depths involved (Lake Superior being as much as 1 300 ft deep in parts, Lake Michigan 920 ft, Lake Huron 750 ft, Lake Erie 210 ft, and Lake Ontario 760 ft), the water temperatures tend to remain relatively constant. Measurements of water temperatures in Lake Superior indicate that the entire body, below a depth of 180 ft, remains at a temperature of approximately 39.4° F throughout the year, which is the temperature of maximum density. In summer, the upper water is at a higher temperature than the lower body of water; and, in general, the temperature becomes increasingly warmer from a depth of 180 ft to the surface. In winter, the upper water is colder than the lower body;

---

[6] Junior Engr., U. S. Lake Survey, Detroit, Mich.

and, in general, the temperature becomes increasingly colder from the lower depths to the surface.

The average wind velocity on the lakes is about 10 miles per hr, which is the 15 yr average for four stations located around Lake Superior, the stations being about 100 ft above the lake surface where the wind velocity is comparable to that on the lake. There is considerable evidence to indicate that the effect of the wind is to cause a circulation and interchange of water between the upper and lower layers of the lake, and that there is some interchange most of the time. The effect of this interchange is to keep the surface temperature, which affects evaporation, cooler in spring and summer than would be the case in a shallow body of water; and, the water temperature lags considerably behind the air temperature in the spring and summer when the air temperature is rising. There is a similar lag in the water temperature in the fall and early winter when the air temperature is decreasing. As far as is known, none of the lakes freezes entirely over in the winter, although such a condition might be possible for a short time.

John R. Freeman, Past-President and Hon. M. Am. Soc. C. E., and others who have studied the subject have made attempts to deduce the lake evaporation from the standard evaporation formulas. Realizing that his results were not satisfactory, Mr. Freeman stated[7] that, "Evaporation is at least a matter of great scientific interest, and a precise knowledge of the causes leading to change in its amount could be of use * * *. The collection of accurate statistics can not be begun too soon." After considerable study, he recommended the following procedure for the collection of data:

(1) A few months of experimental work, with relatively inexpensive equipment, for obtaining accurate values of constants in the formulas, by means of which evaporation can be estimated from standard records of the U. S. Weather Bureau Stations, which give the temperature, dew point, and velocity movement of the air.

(2) At each lake, one, or preferably two, evaporation tanks, on opposite sides (one in Canada and one in the United States) each preferably 6 ft or 8 ft in diameter by 4 ft to 5 ft in depth, of rigid shape, set on a rigid support high enough above the lakes to escape waves, and located on some projecting pier or on the shore. This type of tank should have provision for warming the water in winter barely enough to keep the ice from freezing on the surface, should have a device for agitating the surface slightly, and an anemometer should be set beside it.

(3) One daily temperature measurement shown by the maximum-minimum thermometers should be made along with observations for all the meteorological factors affecting the evaporation.

(4) Comparison should be made between the wind velocities at the pan and those recorded at the regular Weather Bureau Station in the same vicinity.

Because present formulas were not satisfactory for the required determination, new experiments which were more or less in accord with Mr. Freeman's recommendations were undertaken.

---

[7] "Regulation of the Great Lakes," by J. R. Freeman, p. 421.

Description of Equipment

All stations were located near the lake shore away from any buildings or land obstructions which might create atmospheric disturbances. The design and arrangement of the equipment approximated that used by the Weather Bureau as nearly as possible in order to facilitate comparison of data. The dimensions of the pan and relative positions of the instruments were identical. However, the pan had several new features which heretofore had never been used.

Design of Pan.—In order to control and regulate the temperature of the water in the pan, heat had to be supplied in winter and refrigeration in summer. The original design, shown in Fig. 3, called for a water-jacket around the pan where warm or cool water could be circulated. This design was modified in two cases because of local conditions. At Duluth, enclosed electrical heating elements were submerged in the pan water; and at Detroit, electrical heating elements were placed in the de-watered jacket. The supply of heat was regulated by thermostatic control. All units were cooled in summer by circulating cold water around the tank. The supply of cooling water was regulated periodically, by hand, as the need arose. The source of supply was either cold well-water or water pumped from the lake at a depth of 20 ft or more. The pans were placed in large insulated boxes which aided in the regulation of the temperature.

Fig. 3.—Design of Detroit Evaporation Unit

It has been mentioned that an attempt was made to keep the temperature of the pan water as nearly as possible to mid-lake temperatures at all times.

Due to mechanical difficulties, the control was far from perfect; but the results were entirely satisfactory when analyzed by the method which was used and which does not require that the pan water be at the same temperature as the lake water.

Average Daily Temperature.—A maximum-minimum thermometer was placed in the pan water to obtain the mean daily temperature. It was assumed that for all practical purposes the mean of the maximum and the minimum water temperature for the 24-hr period represented the average temperature for the period. As a check on this assumption, observations every half hour for 24 consecutive hours were made on a number of different days. The thermometer was also read for each of these different days. The average of the 48 half-hour readings for each day, in all cases, checked the mean of the maximum-minimum value for the same day within 0.5 degree.

The method of obtaining the average daily air temperature was the same as that used by the U. S. Weather Bureau. The mean of the maximum and minimum thermometers gives the average temperatures, accurately for the day, except in rare instances.

Other Equipment.—The total daily movement of wind over the pan was measured by a standard anemometer placed at the edge of the pan and several inches above the water surface. These daily values were reduced to miles per hour before being used in the analysis. Rain and snow gages were placed around the pan to record precipitation. Wet-bulb and dry-bulb thermometers were supplied to all observers for daily observations of relative humidity and only one reading a day was taken in the immediate vicinity of the station.

Results of Experiments

Because of the similarity of the equipment and the method of obtaining the daily readings, it can be assumed that mechanical inconsistencies and personal errors were reduced to a minimum. For purposes of analysis, all daily observations were grouped according to water temperatures, air temperatures, and wind velocities, regardless of location, it being assumed that the relative humidity and barometric pressure were normal for the particular temperature combination under consideration. For certain temperature combinations, this may not be true; but if a sufficient number of observations are taken within any one range, the average relative humidity value for that range will approach normal. The accuracy of a statistical analysis of this nature depends on the number of observations.

Master Chart.—The daily readings, listed according to temperatures and wind velocities, were arranged again into groups with a water and air temperature range of 5 degrees. For purposes of illustration, one group is described briefly: 44 daily readings—11 from the Duluth station, 14 from Kewaunee, 10 from Detroit, and 9 from the Buffalo station—where the average daily air temperature of each reading was between 40° and 45° and where the average daily water temperature was between 45° and 50°, were included in this group. The centroid of these 44 readings was found and plotted, and the average of these readings was assigned this point. The average wind velocity of the group of readings was found to be 5 miles per hr. Approximately 300 daily readings from the four stations were grouped, averaged, and plotted in this manner. An additional 300 observations daily, scattered throughout the period of the experiments, were not used. These 300 readings represented days during which there was considerable rain or snow accompanied by high winds. Under these conditions, the evaporation pan did not collect the same amount of precipitation as the rain gage, and although individual readings of the evaporation pan "catch" were sometimes high and at other times low, it was decided not to include these irregular observations in the averages because of these discrepancies.

Some groups had as many as eighty individual readings and others had only five. The average wind velocities in the various groups or squares ranged from 4 to 6 miles per hr, with most of the squares averaging 5 miles per hr. Each individual square was studied in order to determine the effect of the wind on evaporation in that square. It was found that the increase in the amount, due to an increase in the wind velocity, did not vary in the same proportion throughout the range of the experiments. The proportion in each square was different and followed a well-defined plan. The value of average evaporation, in those squares where the average wind velocity was either greater or less than 5 miles per hr, were decreased or increased, according to the proportion for the respective square, to correspond to a value of evaporation based on a 5-mile wind.

Contours representing equal lines of evaporation were drawn. Fig. 4(*a*) is the final result of this work representing inches of evaporation per month instead of inches of evaporation per day. Daily values may be obtained by dividing by 30. The curves are based on a wind velocity, measured at one foot above the water surface, of 5 miles per hr. It has been assumed that relative humidity and barometric pressure correspond to the average conditions that existed during the particular period of the year in which the data were being obtained at the four stations. In order to determine whether discrepancies, due to location or methods, existed in the data, charts for each station were made. No irregularities in the slope or position of the contour lines were evident. Fig. 4(*b*) represents values of monthly evaporation with a wind velocity of 10 miles per hr, and Fig. 4(*c*) represents values of monthly evaporation with zero wind velocity according to the formula[8] proposed by Adolph F. Meyer, M. Am. Soc. C. E.

$$E = 30\,(V - v)(0.5 + 0.05\,W) \qquad (4)$$

Temperature Loop.—The range of the two master charts (Figs. 4(*a*) and 4(*b*)) is sufficient to cover average conditions on the Great Lakes, and monthly values of evaporation may be obtained directly from them if the respective mean monthly air and water temperature and wind velocity data are available. It is known that the air temperature for individual days drops down well below the low point of the charts. Should it be necessary to obtain values for extreme ranges in temperature or wind velocities, the curves may be extended; daily observations under extreme conditions have been plotted, and they checked the extended contours very well.

To obtain the monthly values of open-water evaporation for any lake, it is necessary to have accurate information as to the air temperatures over the lake,

---

[8] "Elements of Hydrology," by A. F. Meyer, John Wiley & Sons, Inc., New York, N. Y., 1917, p. 238.

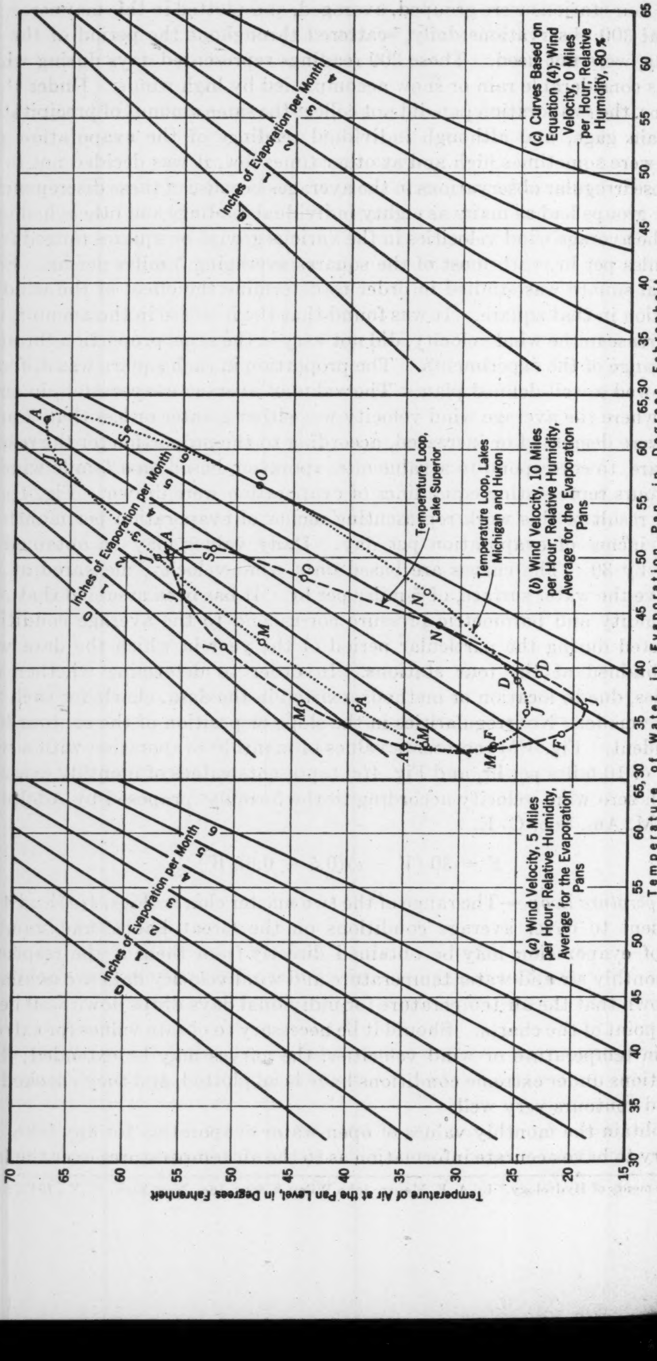

FIG. 4.—MONTHLY EVAPORATION CHARTS

the average water temperatures, and the average wind velocity over the lake. Considerable attention was given to these factors. Mean monthly air temperatures obtained from the records of the U. S. Weather Bureau Stations along the shore of the lakes do not represent mid-lake conditions. Readings observed out on the lake differ materially from those taken on shore because the air is influenced by the temperature of the water, both in summer and in winter.

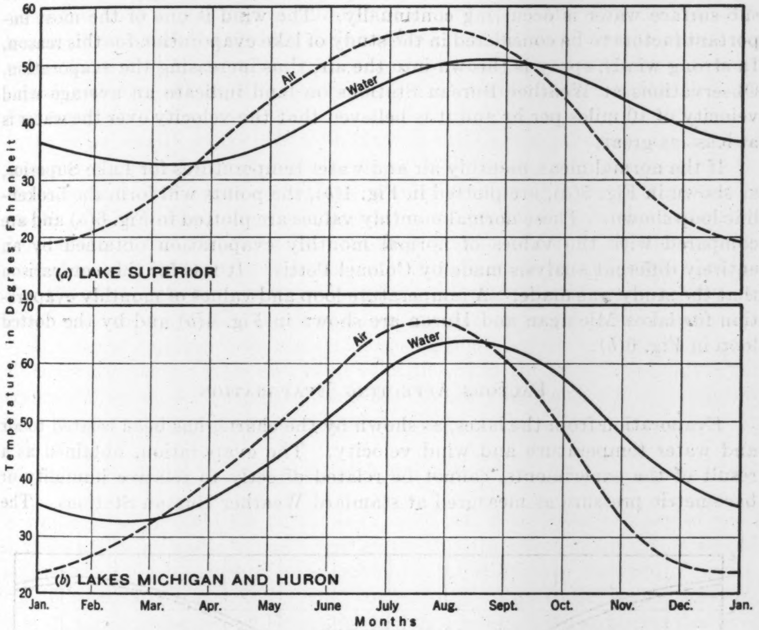

FIG. 5.—AVERAGE MEAN MONTHLY VALUES OF AIR AND WATER TEMPERATURES, WITH OPEN-WATER CONDITIONS

The mean monthly air temperatures as shown in Fig. 5 represent average values deduced from readings observed at the middle of the lake. Information pertaining to temperatures, both water and air, was obtained from the records of Lake Survey steamers, lake freighters, ferry boats, lighthouses, and municipal water-supply departments.

Seasonal air temperature variations in the lake region are considerable, and although these variations are somewhat decreased by the lakes, they do affect the temperature of the water. Large bodies of water, and particularly Lake Superior, react slowly to climatic variations in temperature. In fact, the yearly range of the average mean water temperature as shown in Fig. 5(*a*) is only 18 degrees. Due to the size and depth of the lakes, it can readily be seen that a large amount of heat is necessary to produce temperature changes in the water. The lake is never at the same temperature throughout, at any one time, and the temperature in the middle may be 20° lower than that recorded near the shore. No matter how the air temperature varies, and at what rate, the temperature of the surface water lags behind that of the air. The mean monthly values for lakes Superior, Michigan, and Huron, shown in Fig. 5, represent average open-water conditions.

The surface water is subject to frequent changes in temperature when there is no wind; but since this condition seldom exists, interchange of surface and sub-surface water is occurring continually. The wind is one of the most important factors to be considered in the study of lake evaporation for this reason. In strong winds, spray is thrown into the air, thus increasing the evaporation. Observations at Weather Bureau Stations on land indicate an average wind velocity of 10 miles per hr and it is believed that the velocity over the water is at least as great.

If the normal mean monthly air and water temperatures for Lake Superior, as shown in Fig. 5(*a*), are plotted in Fig. 4(*b*), the points will form the broken-line loop shown. These normal monthly values are plotted in Fig. 6(*a*) and are compared with the values of normal monthly evaporation obtained by an entirely different analysis made by Colonel Pettis. It was for this comparison that the study was made. A temperature loop and values of monthly evaporation for lakes Michigan and Huron are shown in Fig. 4(*b*) and by the dotted loop in Fig. 6(*b*).

FACTORS AFFECTING EVAPORATION

Evaporation from the lakes, as shown by the charts, has been related to air and water temperature and wind velocity. The evaporation, obtained as a result of the experiments, cannot be related directly to relative humidity or barometric pressure as measured at standard Weather Bureau Stations. The

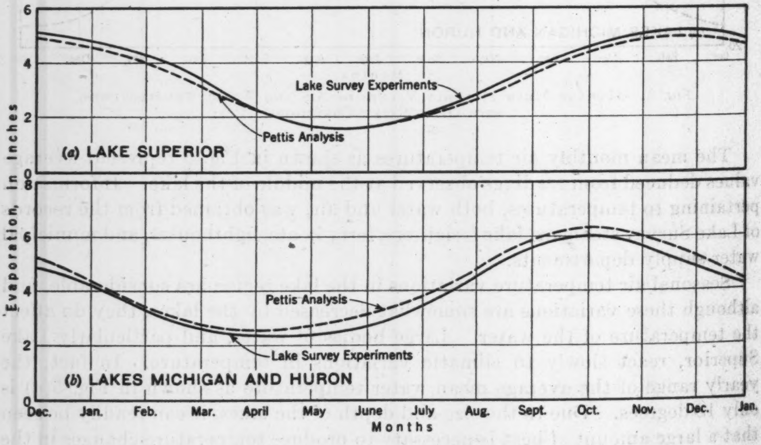

FIG. 6.—EVAPORATION FROM THE LAKE SURFACE

temperature of the air and water influencing evaporation, and likewise the velocity of the wind, may be used with considerable accuracy, but no correlation could be found between evaporation and relative humidity. No evidence could be found that the amount of evaporation varied with either the relative humidity as read at the station or as determined at neighboring Weather Bureau Stations. Although both relative humidity and barometric pressure have not been related directly to evaporation, they have been considered. It is logical to assume that if a sufficient number of observations are made in the same locality, over a sufficiently long period of time, using a particular air-and-water temperature combination, the resulting average relative humidity and barometric pressure will be characteristic for that temperature combination, for that locality.

In other words, evaporation for any month, say September, as obtained from Fig. 4(*b*), is the most probable value of the evaporation for that month, under normal or average conditions of relative humidity for that particular month. This is true since the evaporation curves for this particular locality were obtained from numerous daily readings of evaporation, taken under conditions of relative humidity which existed in this region, in this particular season. Fig. 4(*b*) thus gives the results in the most desirable form to use in any study, either general or specific, which involves average or probable conditions.

In order to emphasize the reason for basing this analysis on the three factors, air and water temperature and wind velocities, it might be well to analyze the ordinary evaporation formula that has been in use for some time.[9] Considering the equation as a modification of Dalton's Law

$$E = K\,(V - v)\left(1 + \frac{w}{c}\right) \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

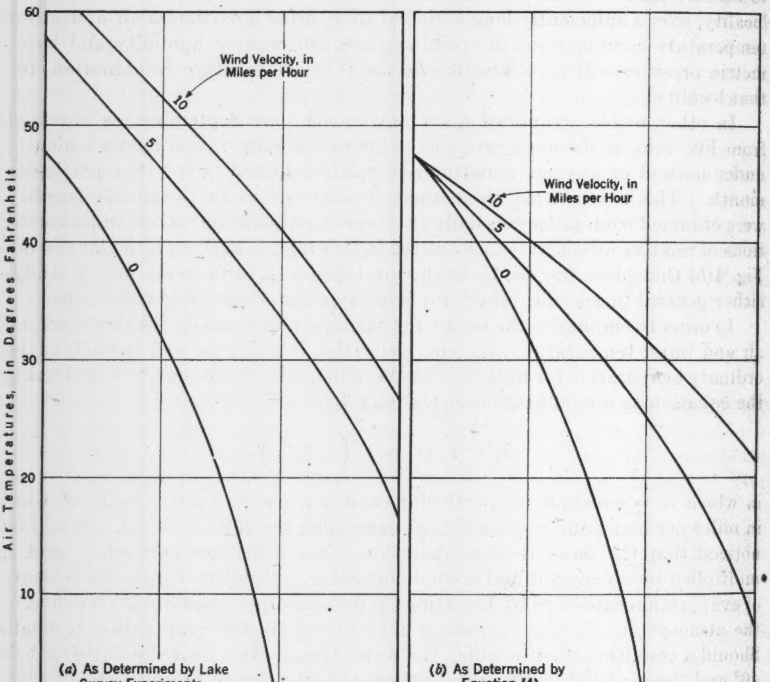
in which K = constant for particular conditions; w = mean velocity of wind in miles per hour; and c = coefficient expressing the effect of wind. It will be noticed that the measure of evaporation is the difference between V and v, multiplied by a constant and a wind correction. In other words, the measure of evaporation expressed by Equation (5) depends upon the saturation deficit of the atmosphere. If the saturation deficit is small, the evaporation is small. Should a condition exist in which the water temperature on Lake Superior was 40° and the air 42.4°, with a wind velocity of 10 miles an hr and a relative humidity of 80%, as measured by the Weather Bureau, a condition quite common for this lake, the evaporation for the day would be zero, according to Equation (5). The same temperature and wind combination on the master chart (Fig. 4(*b*)) would give 0.09 in. of evaporation for the day.

In order to use Equation (5), the temperature of the water and air must be known. After reducing the air temperature to the dew-point temperature, dependent on the relative humidity, each is converted into pressures. It is assumed that the moisture in the air influences the rate of evaporation. This cannot be denied, but experiments indicate that under the influence of wind, evaporation occurs consistently, although Equation (5), used with the proper climatic factor, indicates that the evaporation would be zero. Evaporation increases relative humidity, and it is believed that relative humidity, as indicated by the experiments, is a result of evaporation more than a cause of evaporation.

---

[9] "Regulation of the Great Lakes," by J. R. Freeman, 1926 Edition, p. 135.

Experiments conducted in different parts of the United States by the U. S. Weather Bureau show evidence that a humidity gradient exists, varying inversely as the elevation above the earth's surface. Even if the relative humidity is 100% at the water surface, there is atmosphere directly above where the percentage is less, and there is a continual escape of vapor upwards. It seems logical to assume, for the purposes of this presentation, that evaporation is dependent on temperatures and wind velocities, and that relative humidity on the Great Lakes tends to follow the seasonal averages.



(*a*) As Determined by Lake Survey Experiments (*b*) As Determined by Equation (4)

FIG. 7.—VALUES OF MONTHLY EVAPORATION FOR A CONSTANT WATER TEMPERATURE OF 45 DEGREES FAHRENHEIT

If the wind factor in Equation (5) is considered, it will be noticed at once that E approaches zero as the difference between the vapor tension and the vapor pressure becomes less. When the values of V and v are equal, evaporation ceases, regardless of the wind velocity. Experiments described in this paper show that this is not true. The air temperature is higher for zero evaporation, assuming a constant water temperature, as the wind velocity is increased (see Fig. 7), and similarly the water temperature is lower for zero evaporation, assuming a constant air temperature, as the wind velocity is increased. According to Mr. Meyer,[8] an increase in the wind velocity from zero miles per hr to 10 miles per hr, assuming that other factors in Equation (4) remain constant, doubles the evaporation. With a constant water temperature of 45° F and an air temperature of 32° F, the monthly value of evaporation increases from 3 in. to 4 in., as the wind velocities increase from 5 to 10 miles per hr, relative humidity remaining constant. Similarly at 25° F, the monthly value of evaporation increases from 4 in. to 5.3 in., or an increase in both cases of 33% (see Fig. 7(*b*)). If the same temperature combinations are used with Fig. 7(*a*), it will be noticed that the increase of monthly evaporation, due to an increase in the wind velocity from 5 to 10 miles per hr, for an air temperature of 32° F, will be from 4.2 in. to 5.3 in., or an increase of 26%, whereas the increase at an air temperature of 25° F, for the same conditions, will be from 5.0 in. to 6.1 in., or an average increase of 22 per cent.

At 48° F, the increase, due to an increase in the wind velocity from 5 to 10 miles per hr, according to Fig. 7(*b*), is zero. At this temperature, Fig. 7(*a*) gives an increase in the values of monthly evaporation, with an increase in wind velocity from 5 to 10 miles per hr, of 80 per cent. The wind has been found to have a decided effect on evaporation, particularly when the air and water temperatures are nearly equal. The comparison with the Meyer formula is as accurate as could be made with the data available. The evidence indicates that current opinion as to the effect of wind on evaporation is in need of revision.

With present-day mechanical equipment, much could be learned about the laws of evaporation if tests could be made in a wind tunnel under laboratory conditions. With little effort and expense, all factors governing evaporation could be controlled, each could be isolated and its effect determined.

ACKNOWLEDGMENTS

The data from which the air and water temperature curves were prepared were obtained from the files of the U. S. Lake Survey Office and from information personally obtained by the writer from a number of different sources. Copies of the monthly evaporation reports are on file at the various sectional headquarters of the U. S. Weather Bureau. Mr. Freeman's report[7] on "The Hydrology of the Great Lakes" was consulted frequently.

The data form a part of a thesis[10] by the writer, entitled "Evaporation from the Great Lakes," presented to Lawrence Institute of Technology, Highland Park, Mich., in 1938, in partial fulfillment of the requirements for the degree of Doctor of Engineering. The writer wishes to acknowledge the invaluable assistance of Colonel Pettis and Mr. Sherman Moore, of the Lake Survey, Professors H. L. Woolfenden and G. P. Brewington of Lawrence Institute of Technology; Professor C. W. Chamberlin of Michigan State College, at East Lansing, Mich.; and valuable constructive criticism of Professors C. O. Wisler and W. C. Hoad of the University of Michigan, at Ann Arbor.

---

[10] A copy of the thesis, containing all observational data, has been filed for reference in the Engineering Societies Library, 33 W. 39th Street, New York, N. Y.

DISCUSSION

A. A. Young,[11] Assoc. M. Am. Soc. C. E. (by letter).—The Symposium on Hydrology of the Great Lakes is an excellent discussion of evaporation from large bodies of water under unusual conditions. The quantitative analysis so closely supported by experimental data is proof of the value of the methods involved. An interesting feature is the shape of the evaporation curve which, contrary to evaporation losses from smaller lakes, shows higher rates of loss in winter than in summer.

This agrees with the fundamental law developed by Dalton (see Equation (5)) which, in brief, states that if all other factors are constant the rate of evaporation is nearly proportional to differences in vapor pressure at the temperature of the water surface and vapor pressure of saturated air at the temperature of the dew-point. When water is warmer than air at less than the saturation point, the difference in vapor pressure is favorable for evaporation, which accounts for the greater losses during winter months. Negative vapor pressures may cause moisture held in the air to return to the water surface although the actual contribution will probably be negligible.

The same conditions were observed by the writer in connection with evaporation studies of the Division of Irrigation of the United States Department of Agriculture in a small covered reservoir in southern California to which relatively warm water was pumped from a near-by well. A narrow belt of screen extending entirely around the superstructure of the reservoir permitted some degree of ventilation but prevented marked air currents at the water surface. Average temperatures of water and of air at the water surface were almost exactly the same during August, with the result that evaporation was only 0.9 in. for the month. Contrasting with this was a January loss of 2.50 in. under conditions for which the air temperature was 8° less than water temperature. The monthly evaporation curve for the reservoir was an approximate sine curve only from June to November; the next 6 months plotted as an approximate straight line.

Fig. 1(*e*) in the paper by Colonel Pettis shows permanent land losses of 5.9 in. annually, with a maximum monthly loss of 0.9 in. in August. Definition of land losses is given as "the difference between the rainfall B and the surface and underground flow into the lake * * *," with B indicating precipitation on tributary land areas. Land losses thus include transpiration from all classes of vegetation plus evaporation from moist surfaces.

It would be interesting to know whether the value given to land losses is supported by results of investigations of consumptive use of water by native vegetation and agricultural crops for the area involved. The writer has no data for comparison except estimates by A. F. Meyer[12] of 4 to 12 in. of normal seasonal transpiration for such growth as coniferous and deciduous trees, brush, grains, grass, and agricultural crops. However, investigations of the effect of drought on farm-shelter belts and tree plantations of the northern prairie region in Minnesota, to determine the survival of the principal trees native to the region, following the severe drought of 1934, give an indication of moisture requirements of several tree species.[13] Climatic differences between Minnesota and the Lakes region would appear to be confined principally to differences in humidity which may be favorable to greater consumptive use in the prairie district.

[11] Associate Irrig. Engr., Div. of Irrig., Bureau of Agri. Eng., U. S. Dept. of Agriculture, Pomona, Calif.

[12] "Elements of Hydrology," by A. F. Meyer, John Wiley & Sons, Inc., New York, N. Y., 1917.

Conditions leading up to the drought of 1934 were in themselves unfavorable to soil moisture. Tree plantings were in relatively good condition prior to 1930. From this time on, subnormal precipitation, coupled with depleted soil moisture, induced severe losses for all tree species. During this period a large percentage of the tree population died for lack of moisture. Much of the area is on the critical line of 20 in. of rainfall. When less rain occurred, tree losses ranged from 22% to 73% of the total number of trees investigated. From this it appears that the minimum water requirement of tree growth on the Minnesota prairies is not far from 20 in. annually. This is considerably different from the land losses for the Lakes area and, despite the difference in localities, leads to some speculation as to whether 5.9 in. annually is the total loss.

Evaporation experiments made by Mr. Hickman as a basis for estimating actual losses from the Great Lakes involved much conscientious work. The evaporation pans were set in water baths in which attempts were made to maintain water temperatures the same as mid-lake temperatures. The close comparison of the pan experiments and the Pettis analysis is remarkable when the difficulties inherent to each method are considered.

Some of the drawbacks of the Weather Bureau type of pan used were overcome largely by the temperature control. The principal objection to the Weather Bureau pan lies in rapid changes of the water temperatures, which follow air temperatures more closely than in deeper pans set in the ground. The principal advantage of the Weather Bureau pan is in the opportunity of comparing the long series of records obtained from it under a variety of climatic conditions. Records from the pan used in the experiments cannot be so compared because, in effect, it is a floating, rather than a land pan. Records[14] show the relation of evaporation from small reservoirs or large tanks to be about 0.70 of the Weather Bureau pan loss. Under conditions of temperature control, and with the pan surrounded by water, this value would increase and probably approach unity. It would be a matter of interest if Mr. Hickman had stated whether actual pan evaporation was assigned as direct lake evaporation without use of a conversion coefficient.

Since March, 1936, the Division of Irrigation, Bureau of Agricultural Engineering, U. S. Department of Agriculture, has been experimenting with a specially designed ground pan, 2 ft in diameter, with the object of reducing evaporation losses to a point that will not require use of a coefficient. A new principle is introduced in evaporation experiments. By using a screen to intercept a portion of the rays of the sun, comparisons have been made, since 1936, with other pans of which the most important are the Weather Bureau pan and a ground tank, 12 ft in diameter. Evaporation from the screen-covered pan for the 3 yr of record averaged 80% of that from the Weather Bureau pan and 103% of the 12-ft tank loss. The close agreement between losses from the screen-covered pan and the 12-ft tank demonstrates its value as representing lake or reservoir evaporation more closely than any other known type of small evaporation pan. It has been tested variously from coastal to desert climates with close agreement in results under different climatic conditions. It is inexpensive and easily transported and installed. It also has the advantage of using less water than is required ordinarily, and consequently does not require such frequent attention as other pans.

[13] "Drouth Damage to Prairie Shelterbelts in Minnesota," by M. E. Deters and Henry Schmitz, *Bulletin No. 329*, Univ. of Minnesota Agr. Experiment Station, 1936.

[14] "Evaporation from Different Types of Pans," by Carl Rohwer, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 673.

Mr. Hickman's statement (see heading, "Results of Experiments: Temperature Loop") that: "The lake is never at the same temperature throughout, at any one time, and the temperature in the middle may be 20° lower than that recorded near the shore," calls attention to a condition that perhaps has not been given due consideration heretofore. In estimating lake evaporation through use of a conversion coefficient no attention has been paid to the relation of the water surface in the pan to that in the lake. Contrary to lake surfaces, water surfaces in pans have approximately the same temperature for each unit of water area. Pan surfaces are not greatly disturbed by wind, and losses are not increased by waves throwing spray into the air. This all reduces to the fact that evaporation from pans is practically uniform over the pan area, whereas evaporation from lakes is influenced by many factors that have been given little attention in the past and about which relatively little is known.

For some time the writer has been considering factors that influence evaporation from reservoir surfaces. In the West, water is at a premium and its value is increasing. There are many evaporation pan records but few tests of the value of such records when applied to large water surfaces. Through the courtesy of the Water Department of the City of Pasadena, Calif., a preliminary investigation was undertaken by the Division of Irrigation, on Morris reservoir, to determine evaporative influences for different parts of the water surface. Instruments placed upon barges recorded air temperature, humidity, and wind movement for different sections of the reservoir surface. Evaporation was measured from a small pan on each barge, and lake temperatures were taken. The results indicated wide differences in evaporation and wind movement and significant differences in temperature and humidity. They were thought to be of sufficient value to justify a more extended study over a much longer period to determine further the distribution of those factors affecting evaporation from the larger water surfaces.

Morris reservoir is a narrow, irregularly shaped body of water, surrounded by abruptly rising mountains that influence wind movement and direction, a condition that also influences temperature and humidity. It is representative of many western mountain reservoirs which are different in shape from those in more open country. There is little doubt that size, shape, depth, and surroundings affect evaporation from such water bodies to a considerable degree, and that such factors at present are not included when reservoir losses are estimated.

ALFRED J. COOPER, JR.,[15] JUN. AM. SOC. C. E. (by letter).—Mr. Hickman's paper is an interesting treatise on the subject, and it is with some reluctance that an attempt is made to add to, or detract from, the value of his conclusions. However, the impression is given that some of his statements are based either upon conditions which are peculiar to the Great Lakes region where the experiments were conducted, or upon insufficient data of relative humidity. The purpose of this discussion is to show that, in the Tennessee River basin, there is a marked variation of relative humidity with evaporation (or *vice versa*), as well as the variation of evaporation with wind velocity.

The Hydraulic Data Division of the Tennessee Valley Authority has collected daily evaporation data at four stations in the Tennessee River basin from the fall of 1934 to the present date, 1939. These stations contain equipment in accordance with U. S. Weather Bureau Class "A" evaporation station specifications. A brief description of the two stations from which the data used in the discussion were obtained follows:

Norris, Tenn.—The station is situated at an elevation of 1 000 ft above mean sea level, approximately 20 miles, air-line, northwest of Knoxville, Tenn. It is about 4 000 ft south of the Norris Dam and Reservoir but only 500 ft south of the Clinch River. Observations were started on October 23, 1934, and additional instruments, other than standard equipment, were installed subsequently. These additions are: A weighing evaporation pan, two sets of maximum and minimum water thermometers (one set for each pan), a recording hygrothermograph, a water-temperature recorder (in the standard pan), a recording anemometer, and a barograph.

Murphy, N. C.—The station is approximately 70 miles east of Chattanooga, Tenn., in the town of Murphy, N. C., at an elevation of 1 575 ft above mean sea level. It is about 700 ft north of the Hiwassee River, and at the extreme upper end of the pool to be formed behind the Hiwassee Dam. Observations were begun on November 17, 1934, and since that date the following instruments were added: A recording hygrothermograph, maximum and minimum water thermometers, and a recording rain gage.

The other two stations are at Beetree Dam, N. C., and Savannah, Tenn. Prior to January, 1939, the latter station was situated at Pickwick Landing Dam, Tenn. Data from these stations are in accord with the trend of Fig. 8(*a*) but are not plotted in detail on that diagram.

To confine the study, the range of air temperature was selected arbitrarily as 40° to 46° F, and that of the water temperature as 44 to 50 degrees. A wide variation in relative humidity over this range was found, and a total of 78 points was used. Data of days on which rain and snow occurred were not used, in order to eliminate any possible errors due to differences of rainfall catch between the evaporation pan and the rain gage.

In the Tennessee Valley experiments, wind velocities are measured by an anemometer beside the pan, with the cups about 1 ft above the water surface, in accordance with U. S. Weather Bureau recommendations. As a result, these velocities are smaller than those at the same instant several feet above the ground. In the particular data used, the maximum average daily ground velocity of the wind was 5.01 miles per hr.

---

[15] Hydraulic Engr., TVA, Knoxville, Tenn.

The integrated averages of the daily air temperatures and relative humidities were determined from the hygrothermograph charts. At the Norris station, the integrated daily averages of the water-temperature recorder charts were used, but it was necessary to utilize the daily average of the maximum and minimum water thermometers at the Murphy station. It is believed that no correlation of evaporation and relative humidity is possible when only one daily observation is made of relative humidity unless the relative-humidity curve for the entire day has little or no variation. For any other condition it is necessary to obtain a true daily average by frequent psychrometer or wet-bulb and dry-bulb thermometer readings over 24-hr periods or from a relative-humidity recorder.

Mr. Hickman states (see heading, "Factors Affecting Evaporation"): "The evaporation, obtained as a result of the experiments, cannot be related directly to relative humidity or barometric pressure as measured at standard Weather Bureau Stations," and "No evidence could be found that the amount of evaporation varied with either the relative humidity as read at the station or as determined at neighboring Weather Bureau Stations." The latter statement may be true if it is interpreted exactly as it is written because the average daily relative humidity is obtained only by many readings throughout the 24 hr—not by one or two readings. In the Tennessee River basin it is not uncommon for relative humidities to vary from a minimum of 25% to a maximum of 99% or 100% within 24 hr. With such a variation an observation of relative humidity taken at any time of the day could not represent a 24-hr average, except by chance.

A plot was made of daily evaporation *versus* average daily relative humidity for the data selected. Fig. 8(*a*) shows the points as well as the most likely straight line to indicate the trend. The average wind velocity, in miles per hour, is noted beside each point. For large rates of evaporation there are correspondingly large wind velocities; but for small rates there is a heterogeneous mixture of large and small velocities, in many of which the large velocities approach or exceed those in the higher evaporation "region" of the diagram. It is apparent from Fig. 8(*a*) that evaporation does depend definitely upon relative humidity. The trend toward decrease in evaporation with increase in humidity is clearly shown by the slope of the trend line. It is not intended that this line be construed as representing the equation of evaporation, but rather that it be considered as showing merely the distinct trend of the plotted points. Were there no connection between evaporation and relative humidity, such a scattering of the points would be anticipated that the eye could not envision any trend. For a given evaporation the maximum variation in humidity from the line is 20%, and the average variation of all the points from the line is only 5 per cent. It must be remembered that the other factors influencing evaporation are concurrently active in these field observations and affect the foregoing relationship.

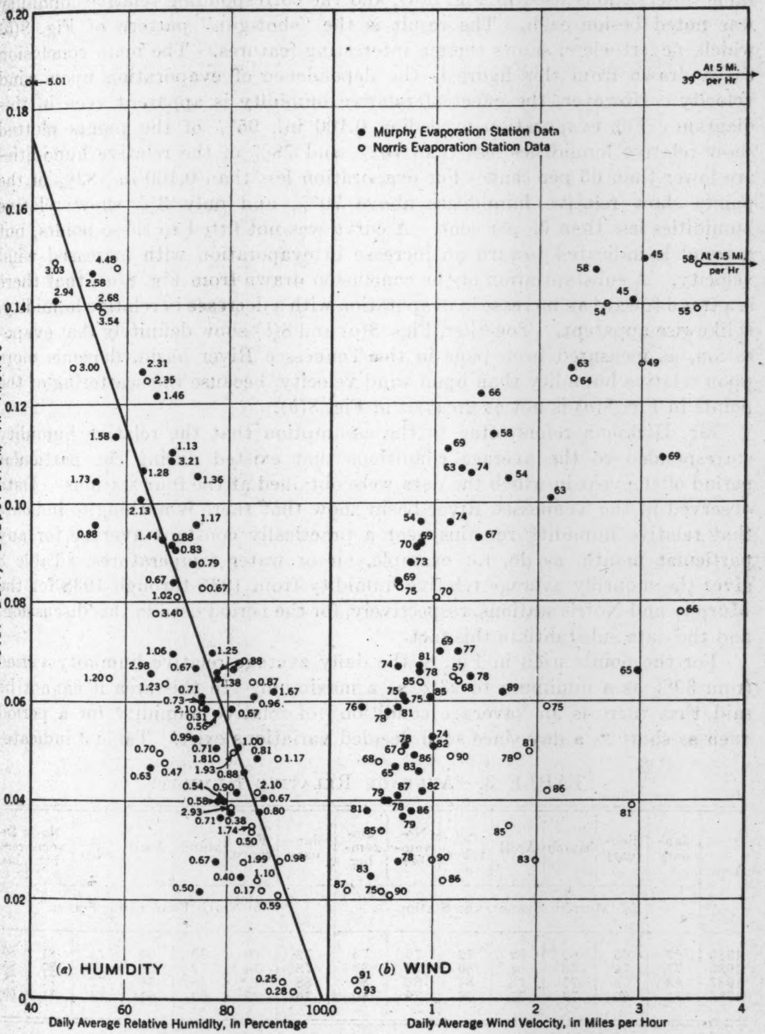

Fig. 8.—Variation of Evaporation with Relative Humidity and Wind

Another plot was made of daily evaporation *versus* wind velocity for the same observations used in Fig. 8(*a*), and the corresponding relative humidity was noted beside each. The result is the "shot-gun" pattern of Fig. 8(*b*) which, nevertheless, shows certain interesting features. The main conclusion to be drawn from this figure is the dependence of evaporation upon wind velocity. However, the effect of relative humidity is apparent even in this diagram. For evaporation exceeding 0.100 in., 95% of the points plotted show relative humidities less than 70%, and 78% of the relative humidities are lower than 65 per cent. For evaporation less than 0.100 in., 82% of the points show relative humidities above 70%, and only 3% show relative humidities less than 65 per cent. A curve was not fitted to these points, but a trend is indicated toward an increase in evaporation with increased wind velocity. A substantiation of the conclusion drawn from Fig. 8(*a*), that there is a trend toward an increase in evaporation with a decrease in relative humidity, is likewise apparent. Together, Figs. 8(*a*) and 8(*b*) show definitely that evaporation, as measured from pans in the Tennessee River basin, depends more upon relative humidity than upon wind velocity, because the scattering of the points in Fig. 8(*a*) is not as great as in Fig. 8(*b*).

Mr. Hickman refers often to the assumption that the relative humidity corresponded to the average conditions that existed during the particular period of the year in which the data were obtained at the four stations. Data observed in the Tennessee River basin show that there is nothing to indicate that relative humidity remains near a practically constant average for any particular month, as do, for example, air or water temperatures. Table 3 gives the monthly average relative humidity from 1935 through 1938 for the Murphy and Norris stations, respectively, for the period used in this discussion, and the data substantiate this fact.

For the points used in Fig. 8, the daily average relative humidity varied from 39% as a minimum to 93% as a maximum. In this area it cannot be said that there is an "average condition" of relative humidity for a period even as short as a day since such decided variations exist. Table 3 indicates such changes from year to year in monthly average relative humidity that it is difficult to consider an average value to be used with measurements of evaporation in a study of field conditions. One wonders whether relative humidity is not one quantity of the atmosphere of which the seasonal trend from year

TABLE 3.—AVERAGE RELATIVE HUMIDITY

Year	January	February	March	April	October	November	December	January	February	March	April	October	November	December

* Report not complete.

to year is erratic and unpredictable, in so far as estimating closely what can be expected for a certain month or season. This variation is dependent largely upon the frequency of rainfall, wind conditions, and air temperatures. These factors then influence the rate of evaporation through the relative humidity they produce.

No definite relationship was found from the barograph charts of the Norris station which would show a correlation between evaporation and barometric pressure. However, daily pressure variations at this station are small—rarely more than 0.5 in. of mercury, which is less than 2% of the mean barometer reading. Results of the evaporation experiments at Fort Collins, Colo.,[16] indicate an approximate increase of 2% in evaporation for each inch of decrease in barometric pressure. Since the maximum variation in pressure at the Norris station is only 0.5 in., the maximum variation that could be attributed to barometric pressure change is about 1 per cent. This variation would be so small that it could not be detected in an observation involving such small magnitudes.

In conclusion it may be stated that the evidence presented indicates that evaporation is influenced by both relative humidity and wind velocity, but with the greater effect being due to relative humidity. It is believed that Mr. Hickman is correct in suggesting that current opinion as to the effect of wind on evaporation is in need of revision—but this revision should be toward giving less weight to its effect and more to that of relative humidity.

ADOLPH F. MEYER,[17] M. AM. SOC. C. E. (by letter).—The subject matter of this Symposium is of recognized importance. There is great need for observations of evaporation from cold water during the summer and from warm water during the winter. The following discussion relates to the Duluth evaporation records and to evaporation from Lake Superior, without reference to conditions on the remainder of the Great Lakes.

In his paper, Mr. Hickman states (see "Synopsis") that "an effort was made to keep the temperature of the water in the pans approximately the same as the temperature of the water in the open lakes"; and (see "Description of Equipment: Design of Pan") that "Due to mechanical difficulties, the control was far from perfect; but the results were entirely satisfactory when analyzed by the method which was used and which does not require that the pan water be at the same temperature as the lake water." It may be quite true that the pan water need not be at the same temperature as the lake water at any given time, but the range of evaporation observations should certainly cover the general range of conditions prevailing on Lake Superior.

An examination of the records filed in the Engineering Societies Library[10] reveals the fact that, at the Duluth station, only about 75 days' records are available which are reasonably applicable to fall and winter evaporation from Lake Superior, including the months of September to February, inclusive. The arrangement for heating the evaporation pan during the winter apparently functioned satisfactorily. In general, the results secured indicate high winter evaporation of approximately the same magnitude determined by the late John R. Freeman,[9] Past-President and Hon. M. Am. Soc. C. E., through the use of the evaporation formula (Equation (5)), utilizing the writer's wind factor.[8]

---

[16] "Evaporation from Free Water Surfaces," by Carl Rohwer, Assoc. M. Am. Soc. C. E., *Technical Bulletin* No. 271, U. S. Department of Agriculture, December, 1931.

[17] Cons. Hydr. Engr., Minneapolis, Minn.

The situation respecting summer evaporation from Lake Superior is quite another matter. No records whatsoever are on file which even reasonably simulate the conditions prevailing on Lake Superior from March to August. At this time, the Lake Superior water is cold and the air is warm.

In Table 4 the lake temperature given in Fig. 5 is compared with the actual recorded temperature of the water in the evaporation pan.

TABLE 4.—COMPARISON OF OPEN-LAKE TEMPERATURES

Month	MEAN WATER TEMPERATURE		Difference, in degrees Fahrenheit	Month	MEAN WATER TEMPERATURE		Difference, in degrees Fahrenheit
	Open Lake	Evaporation Pan			Open Lake	Evaporation Pan	
April	33	41.8	8.8	July	47	68.1	21.1
May	37	53.5	16.5	August	50	69.3	19.3
June	42	62.9	20.9	September	51	57.6	6.6

Observations of pan evaporation, with water temperatures ranging 20° higher in the pan than in the open lake, can scarcely be accepted as a measure of summer evaporation from Lake Superior. This phase of the subject is of the utmost importance, since the main difference between the conclusions of both papers and those of some of the earlier investigators results from differences in summer evaporation, and the assumption of summer underground flow and evaporation being somewhere near equal. This also has a bearing on the conclusion that land losses are only 5 in. or 6 in. a year, as against the normally assumed losses of from 14 in. to 22 in., depending upon precipitation and temperature.

In the paragraph preceding Equation (4), Mr. Hickman states, "In order to determine whether discrepancies, due to location or methods, existed in the data, charts for each station were made. No irregularities in the slope or position of the contour lines were evident."

The writer plotted on a large-scale chart, corresponding to an enlargement of Fig. 4(*a*), all the available daily records of evaporation for Duluth when the wind velocity was between 2.5 and 7.5 miles per hr at the pan level; and there was either no precipitation or less than 0.02 in. The average wind velocity for the plotted points was found to be substantially 4 miles per hr.

The writer then drew on this chart the evaporation lines shown on Mr. Hickman's master chart, Fig. 4(*a*). It appears that about one-third of the daily evaporation observations at the Duluth station plot outside of the limits of Mr. Hickman's master chart. No data whatsoever are available for the Duluth station to form the basis for either the zero or the 1-in. line shown in Fig. 4(*a*). Only a few points are available for the 2-in. line.

A study was made of the 4-in.-per-month evaporation line along which the greater number of the daily evaporation points fell. All of the points lying in a belt extending from half-way between the 3-in. and 4-in. lines to half-way between the 4-in. and 5-in.-per-month evaporation lines were assumed to control the 4-in. line. The average of these points was found to be 0.123 in., or 3.7 in. of evaporation per month. The points ranged from 0.04 in. on March 31 (representing 1.2 in. monthly evaporation, with a southwest wind of 3.0 miles per hr and 92% relative humidity at the U. S. Weather Bureau Station) to 0.28 in. on May 17 (representing 8.4 in. monthly evaporation, with a northwest wind of 7.0 miles per hr and 49% relative humidity).

The second most erratic points ranged from 0.05 in. on March 15 (representing 1.5 in. monthly evaporation, with a northwest wind of 3.6 miles per hr and 72% relative humidity at the Weather Bureau Station) to 0.22 in. on March 9 (representing 6.6 in. monthly evaporation, with a southeast wind of 3.0 miles per hr and 53% relative humidity at the Weather Bureau Station). Another typical low reading was 0.09 in. on April 14 with a northeast wind at 3.9 miles per hr and 95% relative humidity at the Weather Bureau Station. Surely these records indicate the effect of large differences in relative humidity in so far as they reflect changes in vapor pressure in the air.

The points controlling the upper and the lower portions of the 4-in. line were considered separately. The average of those points controlling the upper half of the curve represented 5.0 in. of evaporation per month, ranging from 2.4 to 8.4 in. per month. The average of the points controlling the lower half of the 4-in. line represented only 3.2 in. per month, varying from 1.2 in. to 5.4 in. per month. The lower half represented conditions prevailing during the part of the year when the relative humidity was high.

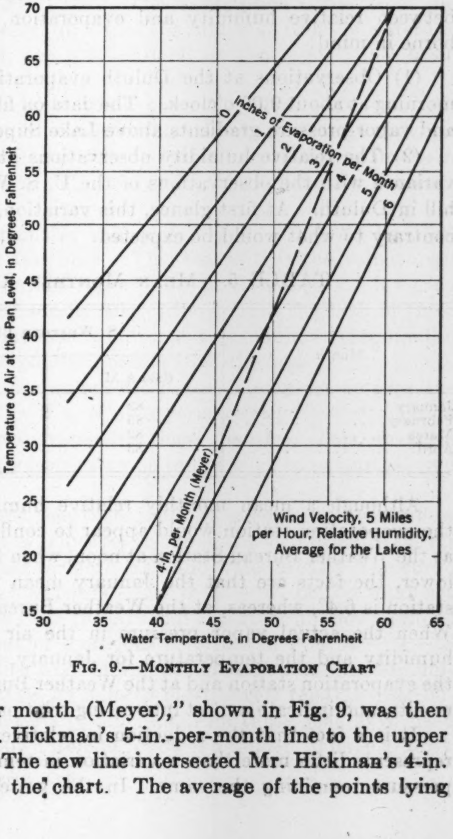

Fig. 9.—Monthly Evaporation Chart

A trial line marked "4 in. per month (Meyer)," shown in Fig. 9, was then drawn from the lower end of Mr. Hickman's 5-in.-per-month line to the upper end of his 2-in.-per-month line. The new line intersected Mr. Hickman's 4-in. line practically in the center of the chart. The average of the points lying within a belt of the same width as that previously used on the author's 4-in. line gave an average of 0.138, or 4.1 in. of monthly evaporation. This is a better average than the author's 3.7 in. for the 4-in. line. Furthermore, the points controlling the upper half of the writer's line averaged 4.5 in. per month, and those controlling the lower half of the line averaged 3.9 in.

A second trial 4-in. line was drawn, starting at the same point at the bottom of the chart, but ending at the 1-in. line instead of the 2-in. line. The average of the points controlling the upper part of this line represented 3.5 in. of monthly evaporation, whereas those controlling the lower part represented an average of 3.9 in. of monthly evaporation. Evidently, if the 4-in. line started at Mr. Hickman's 5-in. line at the bottom of the chart and ended at his 1.5-in. line at the top of the chart, it would probably come nearest to conforming to the data for the Lake Superior observation station. The fact remains, however, that the daily readings are so erratic as to constitute an unsatisfactory basis for any conclusion.

In connection with Mr. Hickman's statement that no relation was found between relative humidity and evaporation, the following facts should be borne in mind:

(1) Observations at the Duluth evaporation pan were made only in the morning at about 9:00 o'clock. The data on file do not cover relative humidity and vapor-pressure gradients above Lake Superior.

(2) The relative humidity observations at the evaporation station are at variance with the observations of the U. S. Weather Bureau situated on the hill in Duluth. At first glance, this variation, illustrated by Table 5, appears contrary to what would be expected.

TABLE 5.—Mean Monthly Relative Humidity

Month	U. S. Weather Bureau		Evaporation Station; 9:00 A.M.
	6:30 A.M.	12:30 P.M.	
January	82	73	63
February	85	70	60
March	82	60	58
April	83	72	64

Although a mean monthly relative humidity of 63% at 9:00 A.M. at the evaporation station would appear to conflict with a reading of 73% made at the Weather Bureau Station at noon, when the relative humidity is normally lower, the facts are that the January mean temperature at the evaporation station is 6.4°, whereas, at the Weather Bureau Station, it is only 3.3 degrees. When the actual vapor pressure in the air is computed from the relative humidity and the temperature for January, it appears that the readings at the evaporation station and at the Weather Bureau Station give nearly identical results, and indicate a most interesting relationship worthy of further study.

It is a fact that the reduction in relative humidity during the day often represents little more than a variation in temperature, with the actual vapor pressure remaining the same. In the writer's judgment, temperature and relative humidity, considered together, as they are in the Meyer evaporation formula (Equation (5)), are a much better indication of the actual vapor pressure in the air which controls evaporation than temperature alone.

S. T. HARDING,[18] M. AM. SOC. C. E. (by letter).—The two papers in this Symposium represent a hydrologic balance sheet for the Great Lakes. The method used is illustrated by its application to Lake Superior. The resulting values found for the individual items in such a balance have values which differ for some items from those more generally considered applicable to similar conditions. The authors' results can be reviewed both from the point of view of their detail procedure and from general comparisons of their results.

As Colonel Pettis states, a rigid solution is impossible where there are three unknowns and only two equations. He meets this condition by means of assumptions which provide the equivalent of a third equation. The correctness of his conclusions thus depends on the correctness of these assumptions.

Colonel Pettis assumes that the area supplying water to Lake Superior is limited to its topographic drainage basin. This assumption is the usual and natural one for this area. Its use requires that the sum of all items of water use must equal, and cannot exceed, the total rainfall on the topographic basin tributary to the lake.

The known items are combined in the expression $P + R - O - S$. Although all of these items cannot be measured completely or exactly they are determinable within reasonable limits. The greatest uncertainty is in the R item as Colonel Pettis states the run-off of only 49% of the tributary drainage has been measured.

The plotting of the average monthly values of $P + R - O - S$ (Fig. 1(*c*)) shows negative values for April and May. This means that the values used for the rainfall on the lake, the surface run-off into the lake and the lowering of the lake are not sufficient to supply the outflow from the lake in these months. This, in turn, means that some additional item of inflow is required to supply the outflow even if no evaporation occurs from the lake.

Although the uncertainty in the values for P and R may account for the negative values found for $P + R - O - S$, all experience requires the inclusion of some material amount of evaporation in these months. This, in turn, results in requiring an additionally larger item of inflow from some unmeasured source.

Proceeding with the assumption that there is unmeasured ground-water flow into the lake, Colonel Pettis derives values for its amount which produce the results shown in his summary balance for both land and water areas. The curve for $P + R - O - S$, in Fig. 1(*c*) which is equal to $E - U$, or the total net value of the unknown evaporation from the lake and any other unknown inflow, indicates that either there are major omissions or errors in $P + R - O - S$ or that other sources of inflow must exist of appreciable amount. It also indicates that the values for evaporation by months must have a relative distribution through the year that is materially different from those that have been usually considered. If the unknown item of inflow is assumed to have a fairly constant distribution through the year, the resulting values for evaporation from the lake must have winter values that are larger than the summer values.

---

[18] Prof., Irrig., Univ. of California, Berkeley, Calif.

Using his assumptions Colonel Pettis completes the analysis to secure the resulting values for land losses, ground-water flow into the lake and evaporation from the lake. Just as Colonel Pettis used his results for $P + R - O - S$ to judge the amount of distribution by months of his unknown items, his conclusions can be used to judge the reasonableness of his results.

The rainfall on the drainage area must supply the land losses, the rainfall penetration which becomes the source of the ground-water and underground flow into the streams and the lake as well as the surface run-off. For Lake Superior alone the items of water supply must balance similarly. If one item is over-estimated some other item must be reduced correspondingly in the land balance. If inflow to the lake is over-estimated, evaporation from the lake will have to be increased.

Some of the limitations on the values that may be secured for evaporation from Lake Superior can be shown by varying the assumed value of the land losses for consumptive use. The total rainfall of 28.2 in. may be distributed in various amounts as illustrated in Table 6. These results illustrate the limitations on the different items. If 16.6 in. of the rainfall on the land are used in soil-moisture evaporation and plant transpiration, including rainfall interception by vegetation, and Colonel Pettis' estimate of stream flow is correct, there is no remaining supply available for ground-water flow into the lake. To meet Colonel Pettis' conclusions land losses can only be 5.9 in. and rainfall penetration would have to be 10.7 in. plus the ground-water portion of the stream flow.

TABLE 6.—DISTRIBUTION OF TOTAL RAINFALL

Description	Pettis	For Various Assumed Values		
Consumptive use, L, in inches of depth on land area	5.9	10.0	15.0	16.6
Inches of Depth on Land Area:				
Surface run-off, R	11.6	11.6	11.6	11.6
Underground flow into lake, U	10.7	6.6	1.6	0
Inches of Depth on Lake Area:				
Surface inflow to lake, R	17.9	17.9	17.9	17.9
Underground flow into lake, U	16.5	10.2	2.5	0
Resulting evaporation from lake, E	35.6	29.3	21.6	19.1

Although no exact values can be set for these items, Colonel Pettis' conclusions differ materially from most of the present values used for these items. He secures a land loss of 5.9 in. where water surface evaporation is 35.6 in. or land losses are only one-sixth of water losses. The drainage area of Lake Superior contains many other lakes. Their total area is not available; if they represent one-sixth of the drainage area, their evaporation would require all of the water assigned by Colonel Pettis to land losses, leaving nothing for loss from the five-sixths of the area in land. For the vegetative conditions of this area, consumptive uses should exceed 5.9 in. The rainfall is sufficient to support active vegetation. Cropped areas would require more than 6-in. loss for usual yields; forest areas would consume in excess of this amount. Colonel Pettis finds a maximum monthly land loss of less than 1 in. per month. General values shown by available records are well summarized by Joseph Kittridge, Jr.,[19] who places the area surrounding Lake Superior in the group of annual water losses between 10 and 20 in. Mr. Kittridge found such losses to be less than 10 in. only in sagebrush and desert shrub areas. Although his method of deriving results includes unmeasured deep ground-water movement with the land losses, his values are derived from areas adjacent to Lake Superior where such deep ground-water movement is not a factor.

The reasonableness of the land-area balance can also be approached from another point of view. All the underground flow to the lake, plus at least part of the surface run-off, must represent rainfall that has penetrated below the plant roots and reached the water table. The portion of the surface run-off that represents ground-water flow into the streams is not discussed in numerical terms in the Symposium and would be difficult to estimate closely. As the stream flow is fairly well sustained throughout the year such ground-water flow appears to be a material part of the measured stream flow.

The quantity of the derived underground flow into the lake represents 37% of the precipitation. With ground-water movement into the surface streams, the summary presented by Colonel Pettis would require that more than one-half of the rainfall penetrate to the ground-water. This is a much larger proportion of rainfall penetration than has been found for other similar areas. The general results of observations of rainfall penetration in the Great Plains area[20] would indicate little penetration from the 28.2 in. of rainfall on heavy soils, to perhaps 6 in. on sandy lands if conditions are as favorable as on the drainage of the Loup River in Nebraska. The probable amount of rainfall penetration on the drainage area of Lake Superior would not appear to be sufficient to account for more than the ground-water flow into the streams which is included in the stream item of Colonel Pettis' water supply balance.

The small value found for consumptive use requires a correspondingly high value for the total run-off. For both surface and underground run-off, the total run-off derived is 22.3 in. from a rainfall of 28.2 in. This exceeds the quantity of run-off obtained from adjacent similar areas. Areas farther west in the same latitude, with about 20 in. rainfall, have a surface run-off of only 2 or 3 in., and have little rainfall penetration.

Evaporation.—The Symposium presents two determinations of evaporation from Lake Superior, separately derived. Their close agreement does not necessarily represent a proof of the correctness of either.

Mr. Hickman's method of observation of evaporation represents a commendable effort to eliminate one of the factors which causes observations with pans to differ from the loss from large water areas. The method used, however, raises additional questions regarding the interpretation of the pan results in terms of lake evaporation.

The maintenance of the temperature of the water in the pans at the same value as the temperature of the surface water in the lake does not of itself assure the same rate of evaporation. Although it may reduce the extent of the difference, comparisons between the temperature-controlled pans and measured evaporation from large areas are needed before the assumption that the controlled pan has a coefficient of unity in all months can be justified. Although the difference in temperature between the water in the pans and in lakes is one of the important factors in their different rates of evaporation, other factors such as rim effects of the pan, differences of exposure and differences in pan size still need to be considered.

[19] "The Magnitude and Regional Distribution of Water Losses Influenced by Vegetation," by Joseph Kittridge, Jr., *Journal of Forestry*, Vol. XXXVI, No. 8, August, 1938, pp. 775–778.

[20] "Direct Accretions to Ground-Water from Rainfall," by S. T. Harding, M. Am. Soc. C. E., *Transactions*, Am. Geophysical Union, 18th Annual Meeting, 1937, pp. 368–371.

Evaporation is dependent on the available heat supply. On the lake the heat supply is primarily that received from solar radiation. The evaporation will be less than the quantity of water that the total solar radiation can convert into vapor because of back radiation and any loss in heat to surrounding bodies. Heat is stored in the lake during months of rising water temperatures and withdrawn during those of lowering temperatures. The authors state that temperature variations extend to a depth of 180 ft. They present the monthly mean surface temperatures but do not show the monthly temperature profiles in the lake.

If the heat added to the pans during the cooling months, to maintain the same water temperature in the pan as in the surface water in the lake, is equal to the heat obtained at the lake surface by the cooling of the lake water, then the loss from the pan would represent the probable evaporation from the lake as far as the heat balance items are involved. In the summer months the heat removed from the water in the pan would need to be equal to the heat stored in the water in the lake. Without records of the heat added or removed from the pan, or of temperature profiles in the lake, comparisons on the basis of a heat balance cannot be made.

Mr. Hickman's results differ from direct observations on other lakes which do not freeze during the winter. On some western lakes conditions permit the same type of analysis used by Colonel Pettis where ground-water inflow or outflow is negligible in amount. Among such lakes in areas of fairly low winter temperatures are Pyramid and Walker lakes in Nevada. These lakes also do not freeze during the winter; both have sufficient depth to be comparable, in this respect, to Lake Superior. Results to 1935[21] show much less relative evaporation during the winter months than are found by the authors. The evaporation and air temperatures of the three lakes are compared in Table 7. For the air temperatures the U. S. Weather Bureau records at the nearest station are used, Lahontan being used for Pyramid Lake and Schurz for Walker Lake.

Until the heat-controlled pan can be tested adjacent to a large water surface for which the evaporation can be determined, the coefficient that needs to be applied to the results with the heat-controlled pan must remain unknown. Although the coefficient might prove to be unity, both for annual and for monthly periods, the writer will venture the prediction that the loss from the heat-controlled pan will be found to exceed that from the adjacent large water area and that the monthly ratios of the pan to the large area will be variable.

---

[21] "Evaporation from Large Water-Surfaces Based on Records in California and Nevada," by S. T. Harding, *Transactions*, Am. Geophysical Union, 16th Annual Meeting, 1935, pp. 507–511.

The size of the heat-controlled pan is also a factor in its amount of evaporation if its performance is similar to other types of pan. Comparisons with different sizes of heat-controlled pans would not be difficult to make; if size were found to be a factor it would demonstrate that the assumption of a value of unity for the coefficient of their pan as used by the authors was not justified.

TABLE 7.—COMPARISON OF EVAPORATION AND AIR TEMPERATURES; PYRAMID AND WALKER LAKES IN NEVADA AND LAKE SUPERIOR

Conclusions.—Colonel Pettis meets the apparent contradiction of negative evaporation in April and May, if the ground-water inflow to Lake Superior is taken as zero, by assumptions which remove that difficulty but lead to improbable values for land losses and rainfall penetration. Mr. Hickman's heat-controlled evaporation pans give values for evaporation which agree with Colonel Pettis' results but, if applied to Lake Superior without correction, lead to the same difficulties in land losses that result from Colonel Pettis' analysis.

Although these two papers represent a commendable effort to determine the hydrologic balance for the drainage area of Lake Superior, the problem does not appear to be solved. Further work needed appears to include: (1) A more direct study of land losses to determine what part of the rainfall may be available for ground-water movement into the lake; (2) perhaps a review and possible revision of the estimated surface flow from the unmeasured portions of the drainage area; (3) comparisons of the heat-controlled pans with large water areas whose evaporation can be measured; and (4) monthly temperature profiles in the lake to determine if cooling in the late fall and winter months can supply the amount of heat required for the estimated amount of evaporation in these months. Although previous estimates of evaporation from Lake Superior may have been too small, Mr. Hickman's estimate, when all factors are considered, appears to be too high. Actually the evaporation from the lake must have a value that can be supplied from the rainfall and leave a consistent water supply available for land losses. Mr. Hickman's results do not appear to meet this standard.

O. E. MEINZER,[22] ESQ. (by letter).—The paper by Colonel Pettis does not discuss the geology and ground-water conditions of the drainage basin tributary to Lake Superior. The area is known to be underlain, for the most part, by pre-Cambrian crystalline rocks which in general are impervious or have only low permeability. In most places these hard old rocks are overlain by a thin mantle of glacial drift which is, in part, water-bearing.

So far as is known, the rocks of this basin do not, except locally, have any artesian structure or other structural features for conveying the ground-water laterally toward the lake. The ground-water is believed to be essentially under water-table conditions, with the water-table sloping toward the streams and branches and not generally toward the lake. If these conditions prevail, a large part of the stream flow is doubtless derived from ground-water, but the quantity of water percolating directly into the lake can be only a small fraction of the 10.7 in. postulated in the paper.

On the basis of the great mass of information that is available in regard to the geology and ground-water conditions of the United States, it can be stated confidently that, for most of the large drainage basins in the United States, the loss or gain of water by subterranean flow is relatively small, and the discharge by transpiration and evaporation approximates the difference between precipitation and stream discharge. In general, the rate of discharge by transpiration and evaporation changes gradually and systematically from one region to another with changes in climate.

Colonel Pettis gives the land losses for the drainage basin of Lake Superior as only 5.9 in. If a larger rate of loss is conceded for the extensive swamp areas and numerous minor lakes within the basin, the rate of loss from the actual land areas would be still smaller. If 10.7 in., the purported value of U, is added to 5.9 in., the purported value of L, the total is 16.6 in., which is approximately the discharge by transpiration and evaporation that would be expected in the Lake Superior basin from the known regional loss.

The writer has not been able to get a clear understanding of the process by which the evaporation from the lake (E) has been estimated or computed in this paper. It is apparently quite conjectural. The value of 10.7 in. for ground-water inflow (U) has been derived merely by subtracting $P + R$ from $O + S + E$. Furthermore, the value of 5.9 in. for the land loss (L) has been derived merely by subtracting $R + U$ from B. Apparently no effort was made to study the actual ground-water conditions.

It would seem that, before the results of 10.7 in. and 5.9 in. can be given favorable consideration, a systematic ground-water survey of the drainage basin should be made, including a quantitative ground-water study of at least one locality that appears relatively favorable for percolation of ground-water into the lake. The quantitative study should include such items as a contour map of the water-table and a determination of the extent, thickness, and coefficient of permeability of the water-bearing beds.

---

[22] Geologist in charge Division of Ground Water, Water Resources Branch, U. S. Geological Survey, Washington, D. C.

R. W. DAVENPORT,[23] M. AM. SOC. C. E. (by letter).—From his analyses, Colonel Pettis reaches the conclusion that, for the drainage area of the Great Lakes, the evaporation and underground flow are greater, and the land losses are less, than the values that have been generally accepted.

The mean annual evaporation from Lake Superior has been estimated in notable investigations of recent years as follows: 22 in. by Mr. Freeman, 15 in. by Messrs. Horton and Grunsky, and 23 in. by Messrs. Hayford and Folse. These results contrast with 35.6 in. obtained by the authors of the Symposium. The substantial excess of the latter value of estimated evaporation over the others is impressive.

Unquestionably, the mean annual rainfall and the mean annual run-off from the land area, 28.2 and 11.6 in., respectively, as obtained by Colonel Pettis, may be accepted as reasonably reliable. The results for outflow from Lake Superior and changes in storage in the lake are determined by methods which are reasonably precise and should be correspondingly reliable. Consequently, Colonel Pettis' further conclusion that underground flow is more and losses are less than generally accepted seems to rest fundamentally on the validity of the values adopted by him for evaporation from the lake.

The writer has participated in rather extensive studies of so-called land (or water) losses, or the difference between rainfall and run-off, in Eastern United States. (The term "rainfall" as used herein includes all forms of precipitation.) The studies were supervised by Gordon R. Williams, Assoc. M. Am. Soc. C. E., under the general direction of the writer.[24]

They were limited to streams in the humid or semi-arid regions of the United States east of the Rocky Mountains. The basic period for which the computations were made is the water year, or year ending September 30. Only records which had continued without interruption for three years or more were used. The basins were also selected with a view to: (*a*) The avoidance of complications due to underground flow, as indicated by large springs or other evidence of material ground-water influence; (*b*) the avoidance of artificial regulation by storage; and (*c*) the availability of a sufficient number of precipitation stations for the reliable determination of the average precipitation in the respective basins. The report[24] gives results for about 200 areas with an aggregate period of record of more than 2 000 years, or an average of about ten years per record.

Table 8 shows a summary of precipitation, run-off, and water losses for areas in the western St. Lawrence River Basin and the adjoining region, as they appear in the report. The water-loss results are plotted in Fig. 10 in order to facilitate consideration in relation to their several geographical positions. The requirements of the study for continuity and duration of the records, freedom from complications caused by artificial regulation of stream flow, and adequacy of the rainfall data caused the distribution of selected basins to be sparse in the region indicated.

As used in these studies, the run-off is the surface stream flow measured at a gaging station, and the rainfall is the computed average precipitation over the drainage area tributary to the gaging station. The difference between these two factors, of course, represents the evaporation and transpiration from the basin plus ground-water outflow from the basin that is not measured at the gaging station, minus ground-water accretion from sources outside the basin which appears in the measured surface flow at the gaging station. The common designation of this difference as water losses, as representing the evaporation and transpiration, is a misnomer to the extent that underground flow is involved in the ways indicated. Adjustments to the water-loss results as computed would be subtractive for ground-water outflow that does not appear at the gaging station and additive for ground-water accretion from outside the basin that appears at the gaging station. Variations in evaporation, transpiration, and ground-water effects, both additive and subtractive, would be reflected in variations in the computed difference between rainfall and run-off.

FIG. 10

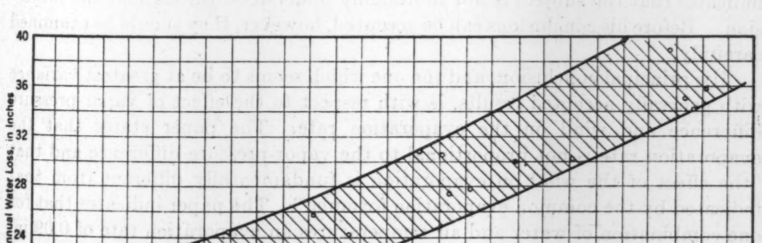

FIG. 11.—COMPARISON OF MEAN ANNUAL WATER LOSS AND MEAN ANNUAL TEMPERATURE FOR SELECTED BASINS WITH MEAN ANNUAL PRECIPITATION IN EXCESS OF 20 INCHES

The water losses show general uniformity under similar climatic conditions and a tendency to systematic transition in value as these conditions change. A striking feature is the progressive decrease in the computed loss in a direction from south to north. In the Gulf States computed losses of 30 in. to 35 in. or more are typical, whereas in the latitude of central New England and Wisconsin the losses seem to range generally from 20 in. to 24 in. In the aforementioned studies data were computed for comparing the mean annual water loss and the mean annual temperature for each of 28 drainage areas selected, with a view to adequacy of basic data and representative distribution.

Fig. 11 is a graphical representation of this relationship by means of 28 points plotted to show the respective basin determinations and lines enveloping them. It shows that for these 28 basins the water losses vary in general with the mean annual temperature. Unless one makes the unreasonable assumption that all of these basins are losing large parts of their water by underground flow, he must conclude that Fig. 11 shows approximately the losses by evaporation and transpiration in relation to the mean annual temperature.

The mean annual temperature of the area tributary to Lake Superior is of the order of 35 degrees. If the relation indicated by Fig. 11 is applicable, it would appear that the normal annual water loss by evaporation and transpiration is between 14 in. and 20 in. This compares with 16.6 in., as obtained by taking the difference between the rainfall and run-off results given by Colonel Pettis, and differs radically from the 5.9 in. computed by him.

Colonel Pettis' determination of evaporation seems to be a likely source of discrepancy, and it is hoped that the work on that factor may receive critical review.

G. H. HICKOX,[25] ASSOC. M. AM. C. E. (by letter).—The writer has read with interest Mr. Hickman's contribution to the subject of evaporation and feels that he is to be commended for bringing it to public attention. The fact that he is able to reach conclusions which vary widely from those held by others indicates that the subject is not thoroughly understood throughout the profession. Before his conclusions can be accepted, however, they should be examined carefully.

His principal conclusion, and the one which seems to be at greatest variance with generally accepted results, is with respect to the effect of vapor-pressure difference and wind on the evaporation rate. The paper states that the evaporation rate is not proportional to the vapor-pressure difference and that "the effect of the wind on evaporation is fundamentally different from that indicated by the common evaporation formula." The paper indicates that for one combination of water and air temperatures an evaporation rate of 0.09 in. per day might occur with zero vapor-pressure difference, the evaporation being due solely to the effect of wind at 10 miles per hr. It is entirely possible that water may be removed from a free water surface by wind when the vapor-pressure difference is zero. Such removal could be accomplished mechanically, the water being carried away from the evaporation pan or reservoir surface in the form of spray. This might easily occur when waves break, for example, the resulting spray being carried away by the wind on the form of minute droplets, without evaporation. There is evidence that such action occurs along the Pacific coast where the accumulation of salt on transmission line insulators several miles inland has become a serious problem. The writer is unable to conceive, however, of 0.09 in. per day being removed bodily from the surface of Lake Superior by this means. Atmospheric turbulence would seem to be the only means of holding the droplets in suspension, and any lessening of wind velocity would result in a noticeable precipitation, it being assumed, of course, that evaporation could not occur.

---

[25] Senior Hydr. Engr., TVA, Hydraulic Laboratory, Norris, Tenn.

Such speculation seems rather idle since the proportionality of evaporation to vapor-pressure difference has been well established. Dalton's Law has been accepted as a basis for correlating evaporation experiments for many years and is apparently sound theoretically. It has also been verified experimentally by Carl Rohwer,[26] F. Graham Millar,[27] B. C. Shepherd, C. Hadlock, R. C. Brewer,[28] and others. The three sets of experiments specifically referred to were conducted under the conditions suggested by Mr. Hickman; that is, "in a wind tunnel under laboratory conditions." The results were in agreement that, for any given wind velocity, the evaporation rate is proportional to the vapor-pressure difference. In these experiments, the vapor pressures were defined in the customary manner—as the pressure of saturated water vapor at the temperature of the water surface, and as the partial pressure of the water vapor in the atmosphere at a considerable distance from the water surface. C. W. Thornthwaite and Benjamin Holzman[29] have computed evaporation rates on the basis of Dalton's Law from observations of vapor pressures at different elevations above the ground surface. They have been successful not only in calculating evaporation rates when a positive vapor-pressure difference existed, but also in calculating the rate of condensation that occurred with a negative vapor-pressure difference.

No theory is any stronger than the evidence that supports it. Before Mr. Hickman's conclusions can be accepted, it will be necessary to refute the contrary results obtained in many carefully conducted experiments, or to explain them in terms of the new theory. It is believed that Mr. Hickman's conclusion regarding evaporation into a wind at a zero vapor pressure can be explained in terms of the accepted theory. His conclusion is apparently based on the improper method of using one daily observation of relative humidity to determine an average vapor pressure for the day. The variation of relative humidity in the vicinity of the Great Lakes is not known, but the point may be illustrated by reference to conditions in the Tennessee Valley. Figs. 12(*a*) and 12(*b*) show a typical example of the variation of relative humidity and air temperature throughout the day at a point in the vicinity of Norris Lake. The corresponding vapor pressure is shown in Fig. 12(*c*). It will be noted that in spite of considerable variation in temperature and relative humidity, the vapor pressure is relatively constant. In general, the actual change of the water vapor content of the air proceeds slowly. At night, when air temperatures are low, the water vapor content may be near saturation. During the day, when the temperature is high, the relative humidity necessarily drops, although the total water vapor (and hence its pressure) may not change greatly. The errors involved in applying a single relative humidity determination to the average air temperature in order to calculate an average vapor pressure for the day are obvious. In the case illustrated, the average air temperature is 63.5° F. Mr. Hickman does not state when the relative humidity was determined, but according to the source material[10] it was 9:00 a.m. Using this time for the data of Fig. 12, the relative humidity is 52% and the vapor pressure for a temperature of 63.5° is 0.77 cm of mercury. The actual average vapor pressure is 0.87 cm of mercury.

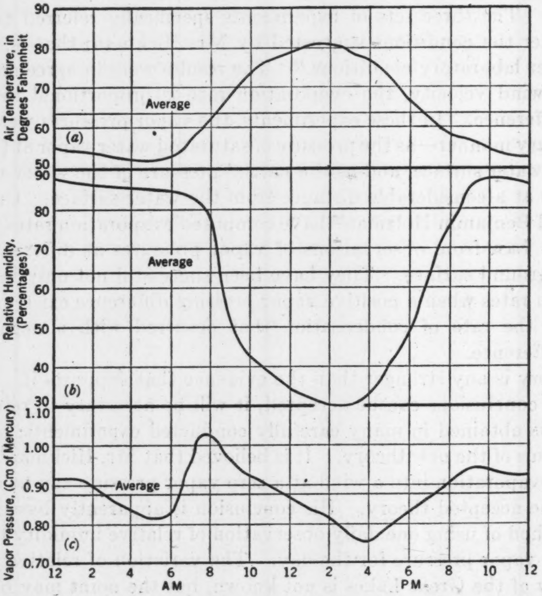

FIG. 12.—TYPICAL AIR TEMPERATURE, RELATIVE HUMIDITY, AND VAPOR PRESSURE NEAR NORRIS LAKE

Even the use of average air temperature and average relative humidity does not give the average vapor pressure, due to the non-linear relationship between vapor pressure and temperature. Referring to Fig. 12 again, the average air temperature of 63.5° F and average relative humidity of 64% give an apparent average vapor pressure of 0.95 cm of mercury, as compared with the true average of 0.87 cm. Similar reasoning applies to the use of average water temperatures to determine the vapor pressure at the water surface.

Dalton's Law is strictly applicable only when the true values of vapor pressure are used. The success of Meyer's formula (Equation (4)) is due to the empirical evaluation of the constants which takes care of the manner in which V and v are calculated. An equation containing constants derived in this manner may give absurd results when applied outside the range of conditions which were used in its derivation. This would not disturb the validity of the fundamental laws on which it was based, and this is where Mr. Hickman "goes astray." It is quite possible to have a definite evaporation rate when the apparent vapor-pressure difference, determined from average air and water temperatures and one observation of relative humidity, is zero. It does not follow, however, that Dalton's Law is thereby proved to be in error.

The foregoing constitutes the chief objection to Mr. Hickman's thesis. The writer disagrees on a number of minor points which will be enumerated in the following paragraphs.

The assumption that "the evaporation from the open lakes, for a given air temperature, water temperature, and wind velocity, would be the same as the observed evaporation from the experimental pans for the same combination of air temperature, water temperature, and wind velocity" (see "Synopsis") is open to serious question. The data of the late Reuben B. Sleight,[30] Assoc. M. Am. Soc. C. E., and Mr. Rohwer[14] indicate that the rate of evaporation is reduced with an increase in the diameter of the evaporating water surface for diameters up to 12 ft. It does not follow that data from a pan 4 ft in diameter can be applied directly to a large lake without correction. This is to be expected from a consideration of the edge effects. Dry air passing over a water surface will take up water vapor more rapidly at the point where it first passes over the water than at some distance farther on. For this reason, the rate of evaporation from a small pan will be greater than that from a larger area.

Mr. Hickman states (see "Synopsis") that "The rate of evaporation from open-water surfaces when the air temperature is below freezing has been investigated for the first time." This statement overlooks Mr. Rohwer's work,[26] published in 1931, in which experiments made under these conditions were described. Mr. Millar's experiments[27] also apparently cover this range. A comparison of the data obtained in these experiments with the records obtained by the Weather Bureau with their standard evaporation equipment would have been greatly facilitated if the same type of equipment had been used. The standard Weather Bureau pan is so mounted as to be exposed fully to sunshine and wind. The desirability of this exposure is open to criticism; but the provision of a water jacket or an insulated shell interferes materially with the similarity of the installation by reducing the transfer of heat through the walls of the pan both by solar radiation and by convection.

The writer is unable to see the reason for omitting relative humidity or vapor pressure as a basis of correlating the experimental results. Would it not be as logical to assume that September evaporation records would be grouped around a certain average value as to assume that any particular daily temperature in September should be accompanied by a certain relative humidity? Certainly it would make the work much easier if all the September evaporation records could be grouped and averaged. Such a value would probably be satisfactory for average conditions.

---

[30] Discussion by the late Reuben B. Sleight, Assoc. M. Am. Soc. C. E., of paper "Evaporation on United States Reclamation Projects," by Ivan E. Houk, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 90 (1927), pp. 303 to 316.

Correlation between the evaporation rate and relative humidity as such is not to be expected in any case. The proper basis for correlation, as predicted from physical theory and verified by experiment, is between the evaporation rate and the difference of vapor pressure. Relative humidity, as implied by the name, is purely a relative term and has no absolute value.

Mr. Hickman's expressed desire for tests made in a wind tunnel under laboratory conditions has already been fulfilled by experiments made by workers in various fields, including the Canadian Meteorological Service, which is also studying the hydrology of the Great Lakes. It is unfortunate that the results of these experiments are not more generally known to the civil engineering profession.

C. R. PETTIS,[31] M. AM. SOC. C. E. (by letter).—Since 1936 the writer has searched for quantitative information about underground water. Harold Conkling, M. Am. Soc. C. E., estimated that 40% or 50% of the rainfall on Long Island reaches the water table; and he stated that probably most of the underground water reaches the sea without coming to the surface.[32] A few engineers in California seem to realize that, at times, ground-water movement may involve appreciable quantities; but engineers in general seem to be almost unanimously of the opinion that ground-water movements are negligible, and can be neglected entirely in the study of the hydrology of any region. Messrs. Harding, Meinzer, and Davenport state the generally accepted opinion clearly and emphatically. Mr. Freeman[7] and Robert E. Horton,[3] M. Am. Soc. C. E., started their studies on the hydrology of the Great Lakes with the assumption that ground-water flow is negligible, and the assumption is carried over into their conclusions. From comments by Mr. Harding it seems that the same was probably done in the study of Pyramid Lake and Walker Lake.

The writer tried to outline the method so that it could be followed by any one who wished to make a similar study; and, in the paper, he gave all of his conclusions that seemed to be of general interest. The statistical studies upon which the conclusions were based[5] were voluminous, and it was not thought that they would be of sufficient general interest to justify publication.

The writer attempted to reach his solution without being unduly influenced by preconceived opinions; but he recognizes that it is fair and logical to ask the question, "Is the value of U too high?" A few remarks will be offered on this question. Necessarily, most of the evidence is circumstantial, but it is cumulative, and indicates that the underground flow, U, is appreciable, and that its numerical value is not much less than the value of the surface flow R.

The underground flow into the lake in the period from April 1 to July 31, inclusive, is greater than the evaporation from the lake in the same period of time. The evidence to support this statement is direct, and is based on only one geometrical assumption—namely, that water which appears in the lake, but which neither falls on its surface nor flows into it from surface streams, must be classed as underground flow. From Fig. 1(*c*), it may be noted that the average value of $(E - U)$ for the period April 1 to July 31, inclusive, is negative (-0.2). This means that for the stated 4-month period the underground flow is greater numerically than the evaporation from the lake surface, both being measured in land units. In other words, if there is any net evaporation from the lake in the average period from April 1 to July 31, there must have been at least an equal quantity of underground flow coming into the lake in the same period, in order to make the water accounts balance.

---

[31] Colonel, Corps of Engrs., U. S. Army (*Retired*), Head, Dept. of Math., Mississippi State Coll., State College, Miss.

[32] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 759.

It is believed that the data may be considered to be excellent and accurate for the purpose of the foregoing statements, and that the statements are true without appreciable error.

The solution in the text indicates that the evaporation from the lake, in lake units, from April 1 to July 31, inclusive, is 6.4 in.; and the underground flow for the same period is 6.6 in., in lake units. This value of evaporation for the stated period checks very well with the results obtained by Mr. Hickman in his analysis of the evaporation experiments.

If an effort is made to check the values of evaporation from standard textbooks, difficulty is encountered. The evaporation experiments which have been made in this latitude[12] (and which have been mentioned elsewhere by Mr. Meyer) indicate an evaporation from April 1 to July 31 (which would mean a corresponding underground flow) almost three times the values given in the preceding paragraph. Mr. Meyer there[33] indicates about 80% more evaporation than in Fig. 1, and Mr. Meyer's chart indicates at another place[34] about 36% more evaporation. The writer's values for evaporation and underground flow for the stated period are the smallest that are consistent with any known published data on the subject.

An abnormally high rainfall, *B*, in any one month will ordinarily increase the surface run-off *R* in the same month, and to some extent in the following months; the effect of the high rainfall on *R* can be computed directly from the data. The effect of a high rainfall on the underground flow *U* can likewise be computed by a method which will be described. The relative effects of the high rainfall on *R* and *U* can be compared therefore.

An abnormally high rainfall in any given month has no appreciable effect on the value of $(U - E)$ for the given month; but there is a strong tendency for the value of $(U - E)$ to be above normal for both the second month and the third month, and this tendency is quite pronounced not only on Lake Superior, but on each of the other Great Lakes.

An analysis of the data with respect to variations in evaporation *E* indicates that temperature is the main factor affecting *E*. Similarly it is evident that rainfall *B* is the principal factor affecting underground flow *U*. Furthermore, over longer periods of time, such as one year, there is no apparent correlation between temperature and rainfall; U and E are independent variables. If a group of values of $(U - E)$ are selected where there was high rainfall in some preceding month, and a similar group following low rainfall in the same preceding month, the difference in values of $(U - E)$ will tend to represent the difference in values of U, since the values of E, being independent, will tend to cancel. The greater the number of items, the more accurate the results from the assumption will be. This method has been used with many different combinations, and the indication is always the same—that high underground flow tends to follow high rainfall, nearly all of the effect being in succeeding months.

---

[33] "Elements of Hydrology," by A. F. Meyer, John Wiley & Sons, Inc., New York, N. Y., 1928, p. 235.

[34] *Loc. cit.*, p. 236.

To illustrate, consider the month of September for the 15-yr period 1920 to 1934. For the years 1921, 1926, 1928, 1929, 1930, 1931, and 1933, the average value of B for September was 4.3 in., the average value of R for October was 0.8 in., and the average value of $(U - E)$ for October was (-1.5) in. For the years 1920, 1922, 1923, 1924, 1925, 1927, and 1932, the average value of B for September was 2.7 in., the average value of R for October was 0.7 in., and the average value of $(U - E)$ for October was (-1.9) in. Subtracting the different items, it appears that in the first period an average monthly excess of 1.6 in. of rainfall, B, produced an increase of 0.1 in. in surface run-off R in October, and an increase of 0.4 in. in underground flow U, for October. Since the value of U was computed for seven values of $(U - E)$ in years of high rainfall, and seven values in years of low rainfall, it is possible that the value of U contains some slight error because the values of E have not balanced. However, if the foregoing process is repeated a number of times, and the results combined for a final conclusion, the probability is that the final results will contain no appreciable error.

The foregoing method was used for various periods of months, and throughout the 15-yr period. For example, high and low rainfall for corresponding periods were compared, for periods varying from one month to twelve months, and the indicated effects on underground flow U were studied for the following months, up to twelve months. The indication is definite and consistent, that underground flow to the Lake increases after high rainfalls. This indication is clear in all of the Great Lakes, for the 15-yr period. It seems that the peak of underground flow into the Lake follows the high rainfall by about six weeks. It then decreases. The study indicated that the effect of a high rainfall on underground flow will not vanish completely for several months.

One calendar month was the unit of time used for all the basic data. Fifteen years was the total period considered for the four Great Lakes. The number of months considered was 720, or 180 months for each Lake. Considering the statistical methods used, the writer is of the opinion that his results cannot be considered to be absolutely accurate; but that they are mathematically excellent approximations, and the error of current engineering opinion about ground-water has been proved beyond a doubt.

In the Freeman report[35] certain reasons are given for believing that the actual rainfall may be greater than that indicated by U. S. Weather Bureau records. More than 100 stations were considered in the Lake Superior area, and most of them are not operated by Weather Bureau personnel. It is believed that most of the errors due to location and other causes would tend to decrease the quantity of rain reported. The writer has seen a rain gage that was dry after a light summer shower. The gage was warm, and the water evaporated almost as soon as it fell. The writer is of the opinion that the actual annual rainfall may have been 3 in. more than the value that was used in his study. The effect of this on the computations would be to add 3 in. to the land losses, without affecting the underground flow.

---

[35] "Regulation of the Great Lakes," by John R. Freeman, 1926.

Mr. Horton has published a summary[36] of engineering opinion about land losses. It is thought that the writer's conclusions about land losses are not inconsistent with Mr. Horton's statements and tables, if local conditions are considered; although the writer's data are slightly on the low side.

The area of Lake Nipigon, on the north shore of Lake Superior, estimated from a small-scale map, is about 1,600 sq miles. All other lakes in the Lake Superior drainage area are relatively small. It is thought that the water surface in the land-drainage area is not more than about 5 per cent. As far as is known, Lake Nipigon and the other lakes freeze in the winter and remain frozen about five months, so that evaporation from them is necessarily much less than from Lake Superior. The writer's data apply to Lake Superior, and they will not apply to localities where conditions are different.

The entire Great Lakes region was covered by glacial drift. Considerable old beach sand is in evidence in places. The writer has made numerous automobile trips covering areas around the Great Lakes; he has talked to geologists and mine operators; and he has found nothing to indicate the impossibility of a large underground flow.

The writer does not claim that he has said the final word, even about Lake Superior. He only hopes that he has offered evidence about a subject on which evidence is needed.

HAROLD C. HICKMAN,[37] JUN. AM. SOC. C. E. (by letter).—During the early stages of the investigation of the hydrology of the Great Lakes certain unexpected relations of negative yield became apparent, which, after making due allowances for errors of observations, could be explained only by unexpectedly large evaporation in winter and correspondingly smaller evaporation in summer. Mr. Freeman had given careful consideration to all available data on evaporation in his study of the hydrology of the Great Lakes, and advised further study of the subject.

Before experiments were begun the writer reviewed most of the work that had been done on evaporation to familiarize himself with conditions under which this work had been conducted, to determine if these conditions were comparable to those in the Great Lakes, and also to determine whether the results of this work could be used in arriving at a suitable and accurate value of evaporation from the lake surface. It was found that conditions affecting evaporation from the lake were quite different from those under which all available accurate data on evaporation from other large bodies of water had been obtained, and very different from the conditions around the small experimental tanks from which formulas and constants for estimating evaporation had been derived.

---

[36] "Hydrology of the Great Lakes," by Robert E. Horton.

[37] Junior Engr., U. S. Lake Survey, Detroit, Mich.

The areas of the water surfaces of the lakes are so large, and the distances across in the direction of the wind so great, that factors affecting evaporation under these conditions must be considered separately. The comparatively mild winters, cold damp springs, cool mild summers, and warm prolonged autumns, characteristic of the lake region, are evidence of the influence of the broad, deep expanse of these waters on climatic conditions. The climate and wind movement, the amount of moisture in the air (which largely affects both radiation loss by night and absorption of heat during the day), the depth of the water which tends to keep the water temperature (as in the case of Lake Superior) between 33° F in winter and 51° F in summer—all are factors in a particular evaporation problem.

The experiments reported in the original thesis[10] were not undertaken to present a new formula, nor to detract in any way whatsoever from the work that had been done previously in this field. They were conducted to determine the best available value for monthly evaporation from the surface of the Great Lakes, using only data which the writer considered as accurate and as having a direct bearing on the rate of evaporation, and excluding from consideration data over which controversy might arise. In the discussions certain objections were raised to the methods used in arriving at a monthly value of evaporation based on water temperature, air temperature, and wind velocity, to the exclusion of relative humidity. Mr. Cooper presents data which show that, apparently, evaporation in the Tennessee Valley was influenced by both relative humidity and wind velocity, but with greater effect being due to relative humidity. He also states that, in his opinion, any revision of current opinion as to the effect of wind on evaporation should be toward giving less weight to wind and more to relative humidity. The writer spent considerable time studying meteorological conditions in the locality in which Mr. Cooper's experiments were conducted and found that, in no degree, did they approach conditions existing in the lake region.

The Tennessee stations were equipped in accordance with U. S. Weather Bureau "Class A" evaporation specifications. The principal objection to this type of installation lies in the rapid changes of pan temperatures. The water temperature tends to follow that of the air and for the purpose of an investigation of evaporation from large cold bodies of water is entirely unsatisfactory. Data obtained with equipment of this type do not make allowance for the large differences between water temperature and air temperature so characteristic in the lake region. It is quite conceivable that the Tennessee experiments would show that evaporation is influenced more by changes in relative humidity than wind velocity when the equipment used and the conditions under which the experiments were conducted are considered. An air mass passing over a body of water at approximately the same temperature as the air will absorb water vapor in quantities depending upon the saturation deficit of that air. At low wind velocities it is evident that the quantity of water evaporated under these conditions would be influenced more by relative humidity than by the velocity of the wind.

In the lake region the air temperature is influenced by the temperature of the lake water at all times. The temperature on shore may be 80° and 5 miles out in the lake it may be 60°. During a large part of the year "thermal" winds blow off the lake. In the winter months a cold dry mass of air, passing across a lake that does not freeze over, tends to "warm up" and consequently the carrying capacity is increased. Under these conditions evaporation would go on during the winter months contrary to all preconceived ideas. That this carrying capacity does exist in winter is evident in the snow belt on the south shore of Lake Superior and Lake Ontario. It is likely that evaporation under these conditions is influenced more by the wind than by relative humidity, as reported by the Weather Bureau Stations around the lakes, and that these relative humidity data cannot be used as a means of determining evaporation from the Great Lakes.

Mr. Cooper states that a few relative humidity readings during the day will not give the average value for that day except in isolated instances. It will be noted that the writer stated clearly that no evidence could be found wherein the amount of evaporation varied with either the relative humidity as read at the station or as determined at Weather Bureau Stations in the vicinity. Mr. Cooper suggests that, because the daily average value was difficult to obtain, it was neglected. It might be well to point out that tests to determine the effect of this factor were conducted extensively before actual experiments began. The average value for the day was obtained by averaging the hourly readings throughout each 24-hr period. Although a number of daily tests were made, four typical separate days may be noted to show the effect of humidity. The first set of two days had an average water temperature for the day of 52° and an average air temperature of 50°. The second set had an average daily water temperature of 56° and an air temperature of 64°. The daily wind velocity for the four days was 5 miles per hr. The evaporation for the days, under the first set, was 0.124 and 0.128 in. with average daily relative humidities of 67 and 85 per cent. The evaporation for the second set was 0.058 and 0.055 in. with respective relative humidities of 73 and 81 per cent. In a number of other instances evaporation continued during periods of complete saturation under a strong wind. Evidence of this kind was found throughout the study and it seems, in the light of these facts, that relative humidity is not as important as hydrologists have generally believed.

The data presented by Mr. Cooper are confined to air temperatures between 40° and 46° and water temperatures between 44° and 50° with wind velocities ranging from 0.5 to 1.5 miles per hr. It would be interesting to see what results could be obtained by including the data from a number of stations with air temperatures ranging from 10° to 95° and with water temperatures from 33° to 75° with wind velocity up to 22 miles per hr.

Although evaporation was found not to be related to relative humidity as reported at the U. S. Weather Bureau Stations, these stations, when the average monthly values were compared from year to year, did show a certain degree of consistency. The average monthly relative humidity for the years from 1920 to 1934 for the Superior Basin was computed by averaging the monthly means as reported by the Weather Bureau Stations at Sault Ste. Marie, Mich.;

Marquette, Mich.; Houghton, Mich.; Duluth, Minn.; and Port Arthur, Ont., Canada.

Table 9 shows the averages of relative humidity for the Superior Basin. Although these data should not be construed as representing open lake conditions they do indicate what changes occur from season to season. Note the regularity of descent from a high in January to a low in May and the progressive increase back to a high in December. If relative humidity does influence evaporation it must vary directly with evaporation in the lake regions as indicated in Table 9 and inversely as shown by Fig. 8 in Mr. Cooper's discussion of the Tennessee Valley.

TABLE 9.—RELATIVE HUMIDITY, LAKE SUPERIOR

Year	January	February	March	April	May	June	July	August	September	October	November	December	Mean
1920	92	86	82	78	64	76	74	76	78	78	85	92	80

1933	84	86	82	72	68	69	73	70	74	80	86	89	77
1934	89	87	82	80	62	72	70	70	83	..	..	..	..
Average	87	86	81	73	68	73	75	76	80	80	83	87	79

It is believed that a seasonal variation in relative humidity, which is rather uniform from year to year, does exist in the lake region. It does not follow, however, that because of this fact evaporation is the same from year to year.

The objections stated by Mr. Meyer were confined to the data upon which the final conclusions were based. He states that no records were on file[10] which even reasonably simulated conditions prevailing on Lake Superior from March to August and proceeds to show that for the summer months of April to September the average daily water temperatures in the pan were from 6.6° to 21.1° higher than those shown by the open lake water temperatures curve and upon which the values of monthly evaporation in the Pettis analysis were based.

The paper describes clearly the procedure used in analyzing the data from the various stations and, as stated, these data are on file in the Engineering Societies Library. The thesis states that[10]

> "one group of 44 readings—11 from Duluth, 14 from Kewaunee, 10 from Detroit, and 9 from Buffalo,—where the average daily air temperature of each reading was between 40° and 45° and where the average daily water temperature was between 45° and 50°, were included in this group. The centroid of these 44 readings was found and plotted, and the average of these readings assigned this point. The average wind velocity of the group was found to be five miles per hour."

When a method of analyzing data of this kind is used, any departure of one station from the average water temperature curve for any one month does not exclude the station entirely from consideration.

In the original analysis, 185 observations, a good portion of which were obtained from the Kewaunee Station, were used, where the water temperatures ranged from 35° to 40°, and air temperatures from 10° to 45°; 193 readings with the water from 40° to 45° and the air from 10° to 50°; 151 readings where the water temperature was between 45° and 50° and the air from 20° to 50°; and 100 readings ranging from 50° to 55° for the water and 35° to 70° for the air. It is believed that this range of air and water temperature does simulate conditions prevailing on Lake Superior.

It must be admitted that the control of the pan water temperature was not all that could be desired. It was extremely difficult to obtain this control, particularly during the summer months, as funds for mechanical refrigeration were not available. The various stations had to depend upon cold well water which did not provide sufficient cooling effect except at Kewaunee. The experiments have been continued with better efficiency and the indications are that the ever-increasing number of daily observations will strengthen the curves materially and add to their range.

It is believed that the analyses of these experiments in conjunction with the air-temperature and water-temperature curves in the paper do give a much more satisfactory value for monthly evaporation from the Great Lakes than any other method or formula presented heretofore.

LARGE CORE DRILLS AID CONSTRUCTION AT CHICKAMAUGA DAM

By James S. Lewis, Jr.,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. J. B. Newsom, J. G. Tripp, James B. Hays, O. N. Floyd, and James S. Lewis, Jr.

Synopsis

The use of large core drills for the purpose of investigating foundations, and for supplementing and verifying the information obtained with small borings, is becoming increasingly common in conjunction with the construction of heavy hydraulic structures. However, the use of these large drills as a direct means of furthering the ends of construction is somewhat unusual, and this paper contains a description of the methods that were successfully used, under difficult working conditions, to obtain a foundation for the upper guard wall of the Chickamauga (Tenn.) Project navigation lock. The equipment and its operation are described in detail, and cost and progress information is included.

Introduction

The preliminary borings, made for the purpose of investigating the site of Chickamauga Dam, near Chattanooga, Tenn., indicated that unusual foundation difficulties would probably be encountered in part of the area covered by the structure. The subsequent excavation in the lock area revealed, however, that with the exception of the up-stream end of the river guard wall, the lock walls could be rested upon ledge rock without unusual difficulty. Under the upper end of this wall, the rock was covered by a heavy layer of over-burden through which it was both unsafe and uneconomical to attempt to excavate, and it was decided to support the piers carrying the wall upon reinforced concrete columns extending through the over-burden and weathered limestone to sound rock.

The guard wall (see Fig. 1) consists essentially of a number of cantilever sections that are supported by piers. Each pier supports a section 42 ft long, 20 ft deep, and 8 ft thick that spans half the distance to the adjacent piers.

Note.—Published in June, 1939, *Proceedings*.

[1] Asst. Constr. Supt., Watts Bar Dam, TVA, Spring City, Tenn.

From its junction with the lock wall, the guard wall is 264 ft long. Each pier is 14 ft by 40 ft in plan at the base, and the side away from the navigation channel is battered so that the top width of the pier equals the thickness of the cantilever wall. This description does not apply to the nose pier, which is rounded on the up-stream side in a conventional manner.

Fig. 2 shows the general plan of the lock, and this structure, with the exception of Piers 27 through 32, was founded directly upon the Chickamauga limestone that composes the massive geologic formation of the region. The information that had been obtained from the early borings caused considerable suspicion with regard to the area to be covered by the guard wall, and additional borings were made when the lock coffer-dam was unwatered. Holes were drilled at the four corners of each of the proposed pier locations, and it was learned that the apprehension that had been felt was fully justified. The over-burden in the area of the piers was found to be more than 60 ft thick in places and was composed of soft clay containing numerous boulders of varying size. Heavy flows of water were not generally encountered in the over-burden, but it was not entirely impervious, and the saturated condition of the material resulted in a lack of stability that would have threatened the safety of any open excavation that might have been attempted.

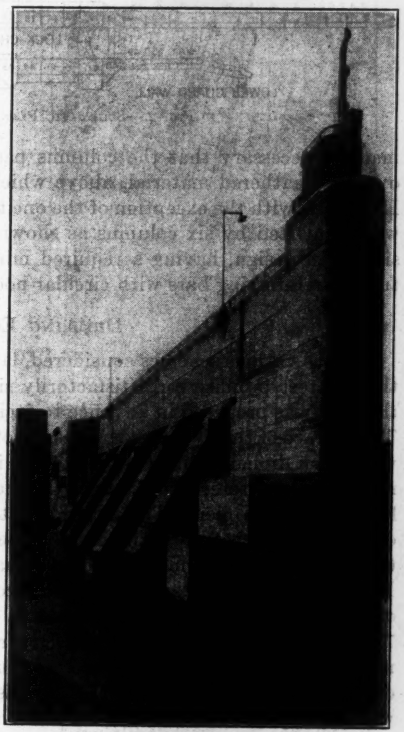

Fig. 1.—Completed Guard Wall

The surface of the underlying ledge rock was of the extremely irregular contour that is typical of weathered limestone and was characterized by frequent pinnacles, pot-holes, and deep, clay-filled crevices. The ledge rock itself was characterized by the existence of extremely sharp folds and numerous faults, and contained well-defined layers of shale and bentonite. The latter was comparatively soft, having little bearing strength when unrestrained, and was frequently found in contact with the shale. Numerous seams and weathered joints and fissures existed to afford passage for the ground-water.

In consideration of the uncertainties and difficulties attendant upon securing a satisfactory foundation of a conventional type under the conditions that existed, reinforced concrete columns, extending through the over-burden and weathered limestone to bear upon sound rock, were chosen as the most economical and satisfactory method of supporting the piers. Sound rock was usually found below a generally prevalent stratum of shale and bentonite that formed a very irregular bed below which the ledge rock was comparatively free from large seams and openings. However, the sharp folding in some areas made it necessary that the columns pass through layers of sound rock that overlay weathered material, above which it was not considered wise to stop. Each pier, with the exception of the one that formed the nose of the guide wall, was supported by six columns as shown in Fig. 3. All of the columns were similar in design, having a required minimum diameter of 36 in., and longitudinal reinforcing bars with circular hoops.

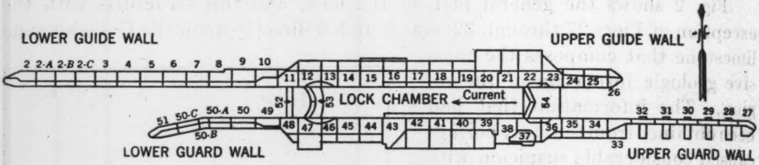

Fig. 2.—Schematic Plan; Chickamauga Lock

Drilling Equipment

Of the various schemes considered, large core drills were selected as offering the greatest promise for satisfactorily sinking the holes for the columns, and the area was prepared in advance to facilitate the operation of the equipment. The surface of the over-burden was so soft and uneven that working conditions were very difficult and, before the drilling was started, a rectangular slab of reinforced concrete, of the size of the pier and 3 ft thick, was poured over the location of each pier. This slab was intended to afford a firm support for the drills as well as better footing for the operators and to prevent the loss of small tools and parts that might otherwise have become covered by the soft mud. Four large drills were used during the course of the work, three of which were originally designed for 36-in. holes, and one of which was designed for drilling 72-in. holes. In order to drill the larger holes required for obtaining the minimum diameter at the bottom of the columns, it was necessary to install 40-hp drive motors to replace the 15-hp units with which two of the smaller drills were equipped. The third 36-in. drill was driven by a gasoline motor. It was found that neither type of driving power possessed any decided advantages under ordinary circumstances. The 36-in. drills were mounted on skids and weighed approximately 3 tons each when fully equipped. They could be moved with the hoist on the drill or with a crane or tractor.

The fourth machine was designed for drilling 72-in. holes and was of much larger size and heavier construction throughout. Instead of being mounted on skids, it was equipped with six wheels designed to roll on rails 8 ft apart, and it was necessary to place track over the location of any hole to be drilled. The spindle was in the center of the machine instead of in the customary position at the end and, as a result, the hole was entirely covered by the drill when it was in the operating position. To remove the tools and core, it was necessary to

roll the drill back upon the track until the hole was clear, when the derrick mounted upon the end of the unit was used for hoisting from the hole. The weight of the drill rods with which this machine was equipped was so great that they were difficult to handle and the progress suffered as a result. As compared with the 36-in. machines, the cutting rate of the large drill was probably greater under similar conditions; but, the time lost in handling the heavy drill rods and in moving and setting up the large machine more than offset this advantage. Under different conditions, where the surface was fairly even and where the holes were placed on a line and spaced closely enough to justify laying a continuous track, the large drill could probably be operated to greater advantage. The weight of the 72-in. machine erected was approximately 9 tons and, to avoid serious loss of time, a crane was always used for moving it to new locations. The various sizes of drills that were used may be seen in Fig. 4.

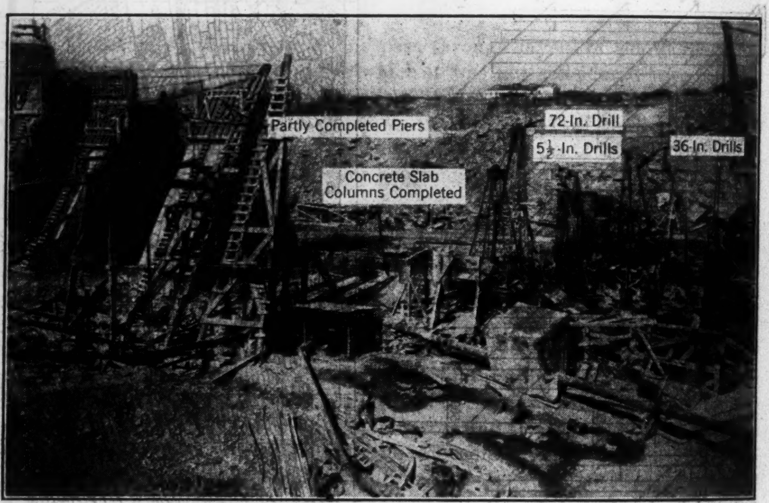

Fig. 4.—General View of Operations

The drills were of the shot type and consisted essentially of a vertical hollow spindle rotated by the power unit through a system of gears, or gears with chains and sprockets. The spindle was connected by hollow drill rods to the bit below. As the bit rotated, shot was transported in a small stream of water through the hollow spindle and rods to the cutting edge. The design of this bit is a matter of importance if the maximum cutting efficiency is to be obtained, and the type found to be most satisfactory is shown in Fig. 5. The liner is desirable for drilling in deep holes, as it prevents the bottom from wearing to a sharp edge under which shot will not remain. Furthermore, as the holes become deeper and the weight of the tools increases, the additional width of the cutting edge prevents the shot from being forced aside, where they are ineffective. The core is cut smaller, giving it less tendency to bind and block in the barrel, and the offset formed by the top of the liner occasionally grips pieces of loose core which are brought to the surface with the bit. The liner is not needed when the holes are shallow. The shot-spreader plate deflects the shot outward so that they fall under the cutting edge rather than on top of the core projecting upward in the bit.

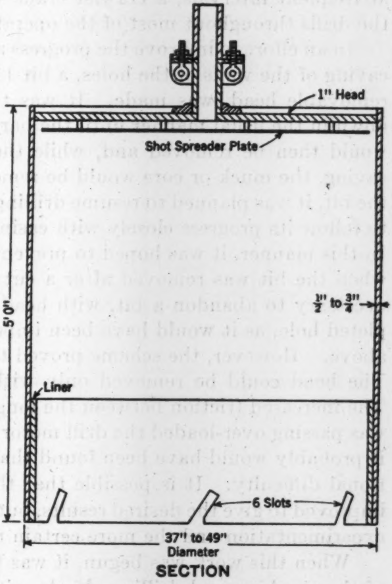

Fig. 5.—Typical Shot Bit for Large Holes

It was required that the columns should have a minimum diameter of 36 in. and, to insure that this size would be obtained at the bottom, it was necessary to begin the holes much larger at the top. The bits varied in outside diameter from 49 in. to 37 in., decreasing in 2-in. increments, and the casing varied from 48 in. to 36 in. inside diameter, also decreasing in 2-in. increments. As shown in Fig. 5, the thickness of the plate from which the bits were rolled varied according to the diameter. The casing was rolled from ¼-in. plate and was purchased in sections 10 and 15 ft long, with a few 5-ft sections. By standardizing upon the sizes indicated, the bit in use always had a clearance of ½ in. when centered in the smallest casing through which it was necessary for it to pass. A clearance of ¼ in. was found to be insufficient, as it was impractical to keep either bit or casing perfectly round, and trouble frequently resulted when the bit could not be passed through the casing.

Operation of Drills

When a bit full of core had been cut, or conditions in the hole made it desirable to stop drilling, the tools were removed so that a man could be lowered to the bottom. Ordinarily, to cut more than 3 ft without removing the bit was considered fair; and a run of more than 4 ft was unusual. After removing the tools, a jackhammer hole was drilled in the center of the core and a pin with hoisting ring was wedged tightly in the small hole. A light charge of dynamite was then placed in the groove on one side of the core and the man was removed from the hole; a strain was taken upon a hoisting line fastened to the pin wedged in the core and the dynamite was discharged. The core could then frequently be raised to the surface with the hoist. If the core did not break at the bottom, so that all of it could be removed in one piece, it was necessary to fire another charge of dynamite beside the remaining core. It was found that a light charge that just sufficed to crack the core gave better results than a charge heavy enough to shatter the rock and make its removal in fragments necessary. Since it was necessary to handle the drills, casing, bits, and cores at frequent intervals, a crawler crane was kept in constant attendance upon the drills throughout most of the operation.

In an effort to improve the progress and to reduce the trouble resulting from caving of the walls of the holes, a bit 11 ft long and 42 in. in diameter, with a removable head, was made. It was thought that this bit could be rotated down in the usual manner until the barrel was filled. The head and drill rods would then be removed and, while the bit supported the side walls against caving, the muck or core would be removed from the inside. After emptying the bit, it was planned to resume drilling without removing it from the hole and to follow its progress closely with casing to insure against caving from above. In this manner, it was hoped to prevent the caving which frequently occurred when the bit was removed after a cut had been made. It would have been necessary to abandon a bit, with head removed, in the bottom of each completed hole, as it would have been impossible to remove it through the casing above. However, the scheme proved to be unsatisfactory for several reasons. The head could be removed only with the greatest of difficulty and delay. The increased friction between the long bit and the material through which it was passing over-loaded the drill motor. If sufficient progress had been made, it probably would have been found that the setting of the casing caused additional difficulty. It is possible that this idea might have been modified and improved to give the desired results, but the pressing schedule precluded further experimentation and the more certain methods were again adopted.

When this work was begun, it was thought that, by following the progress of the mucking and drilling closely with the casing, difficulties resulting from caving of the walls of the holes might be avoided. However, soon after operations were begun, it became evident that the persistent caving of the walls, where the saturated and unstable over-burden was penetrated, was delaying progress seriously, and the heavy flows of water that were encountered in the rock made a complete cessation of drilling necessary at times. The nature of the material composing the over-burden made it impracticable to lower the water-table in the area by pumping from deep holes drilled for that purpose, and it was necessary to take measures to exclude the water in the immediate vicinity of each hole.

ADVANCE GROUTING TO EXCLUDE WATER

Advance grouting in stages was chosen as the system offering the greatest promise of consolidating the over-burden and sealing the openings in the rock satisfactorily, and 5.5-in. shot core holes were drilled and grouted in the center of each column location before the large holes were started. These small holes were grouted at the completion of each stage of drilling so that every stage except the last was subjected to repeated injections of grout under pressure. The depth of the various stages was not determined in advance but depended upon the nature of the material encountered. When it was necessary to penetrate a considerable thickness of over-burden to reach rock, the grouting was accomplished in several stages. The first would be drilled down probably 10 ft and, if the material penetrated was soft, loose, caving, or otherwise unstable, the drill tools were withdrawn, and a 1-in. pipe was inserted to the bottom of the hole. The hole was then grouted through the circulating arrangement shown in Fig. 6. By grouting through the pipe extending to the bottom, the grout in the hole was kept alive, or liquid, at all times, and material that caved from the sides was prevented from permanently blocking off any part of the hole. The pressure in the hole was regulated by the valve in the return line, and a stuffing box in the top of each header allowed the 1-in. pipe to be kept free by raising and lowering it at frequent intervals while grouting. The pipe was composed of 3-ft sections so that, when sticking was threatened, it could be raised and a section removed with only a monentary interruption of the flow. In this manner, the pipe was removed slowly, 3 ft at a time, until the hole refused to take more grout. An effort was made to grout to refusal at a pressure

which varied between 25 and 50 lb per sq in. in the over-burden and as much as 100 lb per sq in. in rock. When surface leaks occurred, the rate of pumping was reduced; empty sacks were packed into any large openings and covered with sand bags. This usually retarded the flow sufficiently to allow the grout to harden and plug the leak. When the first stage was grouted, drilling was resumed through the same hole and extended to such depth as was determined to be suitable for the second stage. The advance grouting was thus carried down in each column location until the cores recovered from the pilot holes disclosed that sound rock had been reached.

In addition to the value of this preliminary work for consolidating the over-burden and plugging the openings in the rock, the pilot holes afforded a reliable means of determining in advance the probable depth to which each large hole would have to be drilled.

For the grouting of the over-burden and rock, a very thick mixture of cement and water containing 3% of calcium chloride by weight of the cement was used. The calcium chloride was added to accelerate the setting action of the cement and thus prevent the grout from traveling to distant areas where it was not needed. It follows that less cement was required. The mixture was handled by air-driven, reciprocating pumps, and the first few batches were ordinarily mixed with a water-cement ratio (by weight) of 0.66. If the hole accepted the grout freely, the ratio was reduced to 0.40 and possibly later to 0.33 if no resistance was offered. Steady pumping was continued until refusal occurred at the desired pressure, or until surface leaks or other contingencies made it desirable to change to an intermittent flow, or to cease entirely. The very thick grout was deemed superior to the more fluid mixtures because of the greater tendency of the latter to open and erode passages through the over-burden. Furthermore, the thicker grout sets faster and probably shrinks less.

The advance grouting, however, did not serve as an infallible means of eliminating the hazard imposed by the ground-water, as there were instances when water later broke into the large holes through over-burden or rock despite all previous efforts to exclude it. The over-burden was definitely consolidated and stabilized to a marked degree, and its density and resistance to percolation were increased. When the grouted material was removed, it was always found to contain a quantity of hardened grout in large pieces, and the clay immediately surrounding the hole was well diffused with unhardened cement. This consolidation of the material surrounding the holes prevented the seeps that often preceded flows of large volume. Following the advance grouting, it was generally true that less trouble from water was encountered in the over-burden than in the rock. This is probably best explained by the fact that in the rock the water followed well-defined channels, whereas in the over-burden it simply caused a generally saturated condition. Thus, when the water followed a narrow vertical fissure or a channel that passed just within the boundary of the large hole, the small hole for advance grouting might fail to intercept the water bearing opening. When the large drill cut into this ungrouted source, of course, the hole was flooded quickly. It was then necessary to regrout the hole by means of a wooden plug which will be described subsequently. Judged as a whole, the advance grouting was quite successful and improved conditions to an extent that made the work possible with the methods used.

DRILLING AND MUCKING

Following the completion of the grouting of any location, a large drill was placed upon the concrete working slab and the hole was started with a 49-in. bit. To avoid confusion, bits were designated by the outside diameter, and casing was designated by the inside diameter. Although all bits were 5 ft long, it was only with rare good luck that sufficient core could be cut to fill the barrel. Blocking of the core, caving of the wall of the hole, or other trouble, usually made it necessary to remove the tools before a full barrel had been cut. A sound, homogeneous rock would no doubt make the use of a longer bit desirable and would result in improved progress by reducing the frequency with which it was necessary to remove the core. The hole was drilled through the concrete slab and into the over-burden with the 49-in. bit until the walls of the hole appeared to be in danger of caving. This distance was ordinarily 10 ft or less. In the boulder-strewn over-burden, the bit would cut a clear opening of the desired size until the 5-ft length was full, or until blocking or binding made it necessary to stop. The bit was then removed and the muck was excavated by hand and brought to the surface by the air hoist on the drill. The removal of the muck ordinarily required more time than the actual drilling as the limited space allowed only one man to work in the hole at any one time. If, after removing the muck to the depth to which the bit had cut, an examination disclosed that the walls were in danger of caving, the exposed part was cased and the size of the bit was reduced for the next cut.

Walls that were apparently safe against caving would sometimes fall in when drilling was resumed and swirling drill water eroded and saturated the standing material. As it was necessary to pump the water from the hole each time that core or muck was to be removed, any seepage through the over-burden tended to increase when the head opposing it was removed. Two-stage, air-driven, centrifugal pumps were used for unwatering the holes as their light weight and compact construction gave them the advantage over other types. The leakage tended to increase as the passages through which the water was flowing were eroded to a larger size, and sudden blow-ins of sufficient volume to interrupt the drilling seriously were not infrequent during the early stages of the program.

In an effort to prevent the blow-ins, the space between the casing and the wall of the hole was well packed with dry cement or dry mortar as each piece of casing was set. The size of the space to be filled varied from practically nothing to several inches, and the type of material that was to be used for packing was determined by the size of the opening. Quick-setting cement was used when the volume of leakage indicated its desirability. It was found that the tendency of small leaks to increase to damaging proportions was eliminated if this space behind the casing was properly packed. When the drilling was in sound rock, the hole was not cased and no unusual precautions were necessary.

Frequently the drill was removed as soon as the bit had cut through the concrete slab, and a light bent, on which an air hoist was mounted, was then placed over the hole. The over-burden was excavated by hand and hoisted to the surface in buckets, casing being set as required. When ledge rock was reached, or when large boulders were encountered, excavation was stopped and it was necessary to wait until a drill could be replaced upon the hole. The progress made by this method, especially when numerous boulders were encountered, was not equal to that obtained with the core drills but, without increasing the unit cost, it permitted the work to proceed simultaneously on a larger number of holes than would have been possible if only the drills had been used. By constantly shifting the drills to the places where they could operate to best advantage, the progress was aided materially.

HANDLING HEAVY FLOWS OF WATER

When heavy flows of water were encountered, despite the precautionary measures taken to prevent them, it was necessary to stop drilling and to move the drill immediately to another location to avoid loss of time. The volume of flow, as judged by the pumping capacity required to handle it, varied from several hundred to several thousand gallons per minute, and prolonged pumping usually resulted in appreciably increased flow. Of the various methods that were tried for stopping these flows so that drilling might be resumed, only one proved entirely satisfactory. First, after striking a heavy flow, a 4-in. centrifugal pump was placed in the hole to learn the depth to which the surface of the water could be lowered by pumping. The size of the hole at this depth was then ascertained and the pump was removed. A laminated, circular, wooden plug, about 12 in. thick, and tapered from botton to top, was made of 3-in. boards, with tar-paper between the layers to reduce leakage. The plug was tapered in order to form a groove for calking against the steel casing, and the diameter was such as to permit the plug to just pass into the hole at the depth at which it was to be set. A 4-in. pipe passing through the center of the plug was connected to the suction of a motor-driven centrifugal pump to form the assembly shown in Fig. 7. This assembly was suspended from a small bent and lowered into the hole with the pump running. A valve in the discharge of the pump permitted regulation of the flow to avoid loss of prime, and this valve was gradually opened as the volume of the incoming water increased with the lowering of the level in the hole. When the plug had reached the intended position, the V-shaped groove formed between the plug and the casing was calked tightly with oakum backed up with wooden wedges. During the calking, and until the plug could be firmly braced against uplift, it was necessary to keep the pump in operation. The total static pressure acting to lift the plug was frequently in excess of 15 tons, and it was necessary to brace to the casing and to weld together, at the laps, the individual pieces of casing above the plug to help carry the load.

When the calking and bracing were completed, the valve in the suction was closed and the pump was removed. The pipe passing through the center of the plug was then extended to the surface and the valve was opened so that the cast-iron foot valve could be broken. A few blows with a heavy rod of reinforcing steel inserted through the suction pipe usually shattered it so that it would offer no obstruction to the passage of grout. A pump was then connected to the pipe so that grout could be forced below the wooden plug and back into the passages through which the water had entered. A small, air-driven, centrifugal pump was always placed on top of the plug while grouting to remove any water or grout that might leak from below and to permit any additional calking that became necessary.

For grouting below the plug, an extra thick mixture with a water-cement ratio varying from 0.40 to 0.33, and containing 3% of calcium chloride by weight of the cement, was used. Once started, the grout was pumped continuously and slowly until no more could be injected at a pressure that exceeded the static head by approximately 20 lb per sq in. The pumping rate and pressure were held down in an effort to avoid wasting the grout by forcing it to distant areas where it was not needed. The calcium chloride, by accelerating the set of the cement, reduced the quantity of grout required to plug the water passages and permitted a resumption of drilling almost immediately upon the completion of the grouting. It was necessary to remove the plug by hand, and the grout filling the hole below it was either mucked out by hand, using paving breakers, or was cored out with a drill. Better progress resulted from the use of the core drills. In every case where the methods that have been described were used, the water was stopped successfully so that no further trouble was experienced in the hole, unless other water-bearing passages were intercepted at a lower elevation. In a number of cases, the water (as evidenced by the quantities of leaves and trash brought in) was entering through passages that extended to the river-bed outside of the coffer-dam. With the normal seasonal flow, the river water stood about 25 ft above the average elevation of the tops of the holes, which meant that it was necessary to work against an appreciable head when water was struck in the lower part of a hole.

It has probably become apparent that the greatest difficulties that arose in sinking the holes were encountered in the over-burden and in unsound, water-bearing rock. Where the rock was sound, and excess water was not encountered, the work became more or less routine. Sound rock was cut smoothly, with a minimum of trouble from blocking and binding, and the core was usually removed in a single piece without difficulty.

When the shale and bentonite bed previously described was passed, or sound rock was apparently reached, a jackhammer hole was drilled 8 or 10 ft into the bottom of the hole to learn whether any openings existed in this zone. A rod of 0.5-in. tool steel, with a 90° hook on the lower end, was used to feel for seams in the small hole. If the rock below was sound or contained only small seams, the large hole was extended no deeper and a pipe was calked into the jackhammer hole to permit the grouting of any small seams later. If the dip or folding of the rock caused the bottom of a hole to slope steeply, it was leveled roughly with a jackhammer.

COLUMN CONSTRUCTION AND TOLERANCES

Upon the completion of drilling, a hole was always filled with concrete as quickly as possible to avoid the constant threat of increasing leakage.

The reinforcement consisted of sixteen parallel steel bars 1 in. sq, pre-fabricated into 32-in. cages not more than 40 ft long. These cages were placed in the holes with a crane and then carefully braced in a position as nearly plumb as possible. A variation not exceeding 1.5 in. from the vertical was allowed when necessary. It was practically impossible to keep the large holes plumb while they were being drilled, as any number of conditions may cause them to turn, and it was necessary to check at frequent intervals so that any deviation might be corrected before it was too late.

A hole could sometimes be plumbed by bracing the drill rods to one side, well above the bit, so that they were thrown into a bow. This forced the bit to lean in the desired direction and the hole could occasionally be righted. More certain results were obtained by reducing the size of the bit sufficiently so that a smaller hole could be started properly. This method was found to be the best if the reduction left enough margin to insure that it would be possible to complete the hole at the required size.

After the reinforcing steel was plumbed and fastened rigidly in position by short steel bars welded to the cage and bearing against the casing, it served as a useful ladder extending the full depth of the hole. This ladder was used to advantage by the workmen while calking the numerous small leaks that usually spouted through the casing joints and for running grout pipes to any openings known to exist behind the casing. These pipes were either connected to nipples welded over holes burned through the casing, or were flattened and forced into any space left where the sections of casing lapped. Despite the efforts made to fill the space behind each section of casing, the material was occasionally washed out by the inflowing water. The grout pipes were placed in order that these spaces might be filled after the columns were poured, affording all possible lateral support for the full length of the column.

As wide intervals of time usually elapsed between the pouring of the first and the last of the columns supporting any one pier, it was feared that the varying degrees of shrinkage, which would have resulted when the columns were loaded, would result in an unequal distribution of stresses in the pier, and cooling pipes were installed to dissipate the heat generated by the setting concrete. The cooling system consisted simply of two vertical pipes connected at the bottom to form a U, through which cool water was forced after the concrete had attained its final set. Resistance thermometers embedded in the columns indicated that a decided drop in temperature resulted when water was circulated.

To fill the holes, concrete was dumped from 3-yd buckets at the surface into a small, steel hopper, with a short guide chute, mounted directly over the hole. Vibrators were used to obtain a proper density of the concrete and to insure that the steel would be well covered for the full length of the column.

Although the columns were 49 in. in diameter at the top where they passed through the slab, the diameter of the upper 18 in. was reduced to 36 in. with a pipe form. Before the first lift of the pier was poured, a cushion of bags was placed upon the offset formed at the reduction. This was done to avoid loading the columns eccentrically, as it was rarely possible to plumb the steel reinforcement so that it was concentric with the upper part of the hole. It was not intended that the slab that served as a working platform for the drills should carry any of the load imposed by the structure.

SPECIAL TREATMENT OF NOSE PIER

The methods that have been described are those which, in general, were used for sinking the columns that support the piers carrying the guard wall. In the case of the nose pier (Pier 27, Fig. 3) it was necessary to vary the procedure that was followed in pouring the working slab for the drills. The excavation of the over-burden at this pier was begun before it was known that it would be necessary to support all of the piers upon columns, and it was soon learned that great irregularity of the rock surface characterized the area. The surface of the rock was found only a few feet below the surface over part of the area of the pier; later it was found to lie as much as 50 ft below the surface only a short distance away. Removal of the first few feet of over-burden released a number of heavy flows of water in the area of the pier, and it was impossible to determine whether it issued from passages in the rock or was traveling in a bed of gravel overlying the rock. Although steel sheet-piling was driven around the pier, the flow continued undiminished, and the great irregularity of the depths at which the piling stopped indicated that the water was probably issuing from crevices and joints through the ledge rock. The total flow into the sheet-pile enclosure was approximately 12 000 gal per min, and it was obviously not feasible to attempt to rest the pier directly upon rock.

In order to obtain a concrete slab upon which the drills could be operated, the area of the nose pier was cleaned up with clam shell and hand labor, and boxes were built around the suctions of three pumps that were left in the enclosure to handle the water. One other pump removed water from a sump excavated just outside of the enclosure. From one particularly bad boil, a wooden-box culvert was carried across the bottom to one of the pumps. Cobbles were then dumped into the water, covering the bottom of the enclosure and surrounding the boxed-in pump suctions until they rose above the water to form a level surface. The interstices between the cobbles formed passages through which the water traveled to the various pump suctions. Vertical grout pipes were installed, leading into the culvert before it was covered, and at random in the cobbles as they were placed. The surface of the cobbles was covered with small stone and the first lift of concrete was poured, using the steel pile enclosure for a form. In order to improve working conditions by bringing the level of the concrete up to that of the surrounding area, another lift was poured later, through which holes were formed for the columns.

Before the drilling for the supporting columns was begun, the pumps were removed and grout was forced into the cobble bed through the pipes that had been provided for that purpose, the wooden culvert being filled at the same time. Subsequent inspection, made when the large holes were drilled, revealed that the cobbles had been well stabilized by the grout. Each column location in the nose pier was grouted in advance in the same manner as has been described for the other piers.

CONCLUSION

In selecting the methods that were chosen for obtaining a foundation for the wall, full cognizance was taken of the fact that much was unknown concerning the practicability of drilling large holes in the type of material that was to be encountered and some doubts were felt as to the economy of the choice. However, cost and progress records which have been compiled since the work was completed indicate that, of the methods considered feasible, none would have proved as economical or as expeditious as the one selected.

Using these methods, 39 holes of an average depth of 55.1 ft and a maximum depth of 82 ft were completed. A total of 2 147.2 ft was drilled of which 1 039.9 ft was in over-burden and 1 107.3 ft was in rock. During a typical operating period of one month, when the obstacles and difficulties encountered were about average, the progress amounted to 10 ft per drill per 24-hr day, or 0.417 ft per hr. At this rate of drilling, the direct labor charge for a crew consisting of driller with two helpers, mechanic with two helpers covering all drills, and foreman is $8 per lin ft. Hourly rates of pay were as follows: Foreman $1.25, drillers $1, mechanics $1.10, and helpers 75 cents and 60 cents. Power, water, air, shot, casing, shop repairs, other services, depreciation of drilling equipment, and overhead should exceed these values somewhat, and a total cost of between $18 and $20 per lin ft is approximately correct. Under different conditions, where the drilling could be done from the surface of the rock, and where the hazard of excessive flows of water did not exist to make casing necessary, it should be possible to reduce the unit cost appreciably.

Observations made since the piers were fully loaded have not disclosed any evidence of settlement of the foundations or of deflection of the guard wall that is carried by the piers.

The operations described herein were conducted 24 hr per day in four 6-hr labor shifts and, despite the numerous delays that were suffered when water broke into the holes and made a cessation of drilling necessary, the work was completed in time to permit the lock to be opened for navigation when scheduled.

ACKNOWLEDGMENTS

The Chickamauga Project Navigation lock was built by the Tennessee Valley Authority with its own forces: T. B. Parker, M. Am. Soc. C. E., Chief Engineer of the Tennessee Valley Authority, Lee G. Warren, M. Am. Soc. C. E., Project Engineer, with James B. Hays, M. Am. Soc. C. E., Construction Engineer, and Mr. F. C. Schlemmer, Construction Superintendent. Mr. H. R. Johnston was in charge of the work described at its inception and was succeeded by the writer. Jack C. Evans, Jun. Am. Soc. C. E., Mr. G. A. Carlson, and Mr. H. E. Murray each supervised the operations on 8-hr shifts.

DISCUSSION

J. B. Newsom,[2] **Esq. (by letter).—Most engineers do not understand that drills which will bore holes large enough for a man to enter can be used in any ground, from the loose water-bearing ground containing some boulders described in the paper, to the hardest rocks known to the mining industry. In the work described, it was necessary to use casing. Diameter was lost every time it was placed, so that a hole which started 4 ft in diameter might be 3 ft in diameter at the bottom. In boring a hole 1 125 ft deep in California in 1935,**[3] **the hole went through heavy ground and gouge which had to be supported without losing size. This was accomplished satisfactorily by using an expanding steel form, behind which quick setting concrete was packed. These large drills are capable of higher development and have a much wider field of possible usefulness than is generally recognized.**

J. G. Tripp,[4] **M. Am. Soc. C. E. (by letter).—The difficulties encountered in sinking relatively small shafts in the over-burden, broken, and solid sedimentary rocks at Chickamauga Dam are outlined clearly in this paper. The methods chosen by the engineers, and the costs achieved, deserve commendation.**

There were probably three methods open to the builders to complete satisfactory foundations under the lock guide wall:

(1) The shot-drill and casing method (that chosen);

(2) The standard "air" method; and

(3) The rotation water method, more or less successfully used in very deep foundations in several difficult locations in and around New York, N. Y.

It appears clear that method (1) was chosen on account of a desire to explore the ground, equipment availability, and operating personnel. If the costs given are the actual totals, there is little doubt that the choice was wise. Under standard "air" conditions, costs would have approached twice those achieved. The rotation water method, if available, would have cost about $20 per ft.

However, the third method deserves mention. Shafts averaging 55 ft with a maximum depth of 82 ft have been driven successfully in Manhattan, where broken rock, boulders, quicksand, and rip-rap were the materials encountered. Also caissons 8.5 ft by 110 ft were sunk successfully across the Connecticut River.

This method consists of a caisson rotating in a column of water. The water enters the caisson under controlled pressure and the lighter and smaller materials pass under the bottom of the cutting edge of the steel shell and appear at the surface annularly about the caisson. Those elements too large

to pass are left in the caisson and removed from time to time, as required. A properly designed cutting edge cuts into the solid rock for any desired distance, say, to 4 ft, when rotation is stopped; the materials surrounding the caisson are then allowed to settle and consolidate, and the caisson becomes ready for unwatering and for concrete. This method obviates the necessity of grouting except in the bottom rock should conditions require. Standard methods accomplish such grouting and a safe steel-cased shaft is ready for steel reinforcement and concrete.

In conclusion, if relatively solid rock had existed from the grass roots down, no shafts would have been needed. In the case at Chickamauga Dam the engineers were faced with the common ailments of all limestone dam sites; that is, corrosion, eroded contacts, and redeposited, tilted, folded, and faulted strata with consequent water problems. In such ground little useful knowledge can be obtained from ordinary core borings. In such cases, the large core drill is indispensable, because an inspection well that the geologist or foundation designer can actually go down into gives all necessary predesign information with certainty. Finally, it would appear that the difficulty of ascertaining foundation conditions under the guide wall at Chickamauga lock led inexorably to the choice of method described.

James B. Hays,[5] M. Am. Soc. C. E. (by letter).—One of the most difficult operations necessary to secure a satisfactory foundation at the Chickamauga Dam is described in this paper. The author demonstrates the fact that exploration in limestone rock must be thorough.

The original borings were not spaced closely, and in the area covered by the work described by the author there was only one hole directly under the wall, with two or three close by. It was realized that the foundation was not particularly good; but it was not until work had been started and excavation for the lock walls was well under way that the real situation developed. Preliminary borings were put down at the corner of each pier, and the detailed information, with other experience on the project, indicated that open excavation to rock would be practically impossible. The coffer-dam was too close to allow open cuts without timbering. Timbered shafts would have exposed too much surface to the mud and clay seams which, in time, would have required excessive bracing and involved considerable leakage. As a result the design was revised, as shown, to support the piers on reinforced concrete columns on rock, since most of the equipment necessary was already available.

Mr. Lewis was placed in charge of this particular feature which was one continuous battle from start to finish against water and mud, and the danger of blows. However, when finally ready for concrete, the holes were in excellent shape so that the leakage caused little, if any, trouble in concreting.

Evidently the cooling of concrete placed in the columns was successful. The writer recalls that one column was shortened more than $\frac{1}{8}$ in. by the circulating cold water. This work was done during the late winter months; hence the river water was used for cooling.

---

[5] Constr. Engr., Kentucky Dam, TVA, Gilbertsville, Ky.

One lesson that was demonstrated on this project was the fact that exploration holes in limestone formation should be spaced closely and drilled accurately; and they should be carefully "logged" by a competent geologist. A second lesson was that grouting of coffer-dams in such a formation was necessary. The work described by the author was in the first of three stages of river coffer-dams. Coffer-dam grouting was started too late in the first stage to be a complete success, although it did benefit to some extent. The second and third stages were grouted thoroughly and, as a result, were remarkably dry. During the construction period, the geologist, Portland P. Fox, Jun. Am. Soc. C. E., was of great assistance in defining the detailed rock structure. Fig. 3 is one of many that were used.

The large core drills were useful for checking the results of grouting and foundation treatment for shafts and pump sumps.

O. N. Floyd,[6] M. Am. Soc. C. E. (by letter).—A rather complete account of a difficult piece of work, planned and executed with very limited guidance from precedent, is presented in this paper. The frankness with which the limitations of the equipment and the failure of certain attempted methods are treated adds materially to its value.

The writer wishes to call particular attention to the added value of these large holes to the engineer, in that they make it possible to see the rock in place. The bedding planes, thickness of cored strata, and any bentonite or clay seams or open cavities are all there to be examined and probed. It was quite helpful, in the work described by the author, to be able to see the rock on which the columns were to rest and also to judge better the lateral support the columns would have because of the developed thickness and probable extent of the large blocks of limestone penetrated on the way down.

The 36-in. holes were helpful in determining the extent and nature of some bentonite seams under parts of the main walls of the lock at this same job. Furthermore, in the cut-off under the earth wings of this dam, where much bad rock had to be removed and a few deep caverns had to be cleaned out and filled with concrete, the 36-in. holes were used for working shafts during the cleaning operations and later for refilling with concrete. Both the cost and the time for sinking shafts in this manner were very favorable.

Another place illustrating the superior value of the larger holes was at one of the early small core drill holes under the south earth embankment of the Chickamauga Dam which indicated a rather deep nest of boulders, clay, and gravel. A 36-in. hole sunk to include this hole showed that the small drill had gone down about a foot away from the almost vertical face of a solution channel in the rock and, since several of the more resistant strata were protruding from this face, they had been cored or broken off and classed as boulders in the record of the first hole.

[6] Cons. Engr., Dallas, Tex.

James S. Lewis, Jr.,[7] **Assoc. M. Am. Soc. C. E.** (by letter).—The discussions have revealed an appreciation of the difficulties often encountered in obtaining satisfactory foundations in limestone. Extensive weathering, solution, erosion, and geologic disturbance frequently have combined to produce a condition which is not disclosed by generally accepted methods of exploration. The erratic results obtained from small borings may prove very misleading and difficult to interpret, and even large borings will leave much essential information to be revealed by the excavation.

As emphasized by Mr. Hays, the services of a geologist skilled in interpreting the information obtained from borings were used to excellent advantage. The aid rendered by Mr. Fox proved invaluable. Mr. Floyd indicates the value of large core holes as shafts for various purposes, and their usefulness also has been demonstrated in mining operations where it was necessary to attain great depths.

There is no gainsaying Mr. Newsom's statement to the effect that large drills are capable of higher development. This is true of shot drills of all sizes, as they have not enjoyed the mechanical refinements that have been applied to the best diamond drills. A reduction in weight would afford greater ease of handling over the rough terrain that must frequently be traversed, and a closed type of construction would prevent the damage that follows when shot get into the moving parts. An automatic shot feed, powered by a standard water meter, was developed at Norris Dam. The immediate effect was a reduction in shot consumption to 25% of the former quantity, a smooth core and hole of uniform size, and less wear on the drilling tools. There is still opportunity for great improvement.

Different methods of obtaining a foundation might have been chosen, as suggested by Mr. Tripp. The writer doubts, however, that the caisson used in the rotation water method could have been used economically to cut the limestone encountered for the distances required.

In describing the use of large core drills for sinking shafts under extremely adverse conditions, the writer's chief desire was to reveal the adaptability of the equipment when the drilling was supplemented by grouting. It is obvious that the methods described would have been impractical without sealing the rock and overburden against excessive leakage.

BEACH EROSION STUDIES

BY EARL I. BROWN,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. MORRIS N. LIPP, GEORGE A. SOPER, JAMES J. O'ROURKE, ELLIOTT J. DENT, RALPH F. RHODES, CHARLES T. LEEDS, AND EARL I. BROWN.

SYNOPSIS

Items of information considered necessary in a comprehensive beach erosion study, the reasons for desiring each particular item, and some general observations on design of protective works are offered, in some detail, in this paper. The presentation is made for two reasons: (1) That engineers interested in beach protection may have the advantage of experience gained by the Beach Erosion Board, United States War Department (under the Chief of Engineers, U. S. Army), as to factors involved in a study of beach erosion; and (2) that the items of information now believed best suited to the purpose by the Board may be the subject of full and free discussion by all engineers interested.

BEACH PROTECTION STUDIES

The science of beach protection is comparatively new in the United States. The rapid growth of seashore resorts and the immense investment therein since automobiles and good roads have made them easily accessible have resulted in a demand for improvement and stabilization of old beaches, and development of new ones. In the past, as each seaside resort developed, local judgment determined the proper method of improving and stabilizing its beach. There resulted a wide difference in character and design of protective structures. Some have proved effective, others have been useless, and still others have done more harm than good.

Each locality presents a different problem. In all cases there is need for detailed and accurate information on local conditions. It is inadvisable to prescribe a given plan of protection for a beach simply because it has proved effective elsewhere, unless conditions can be shown to be similar. If engineers along the coasts can be encouraged to develop a general understanding of the character of information necessary for designing protective systems, and the

---

NOTE.—This paper was presented at the meeting of the Waterways Division at Jacksonville, Fla., on April 21, 1938, and published in January, 1939, *Proceedings*.

general principles of design, a large field opens for them in undertaking beach erosion studies and designing protective works for private property owners. A suggested outline for a report on beach erosion studies is given in the Appendix.

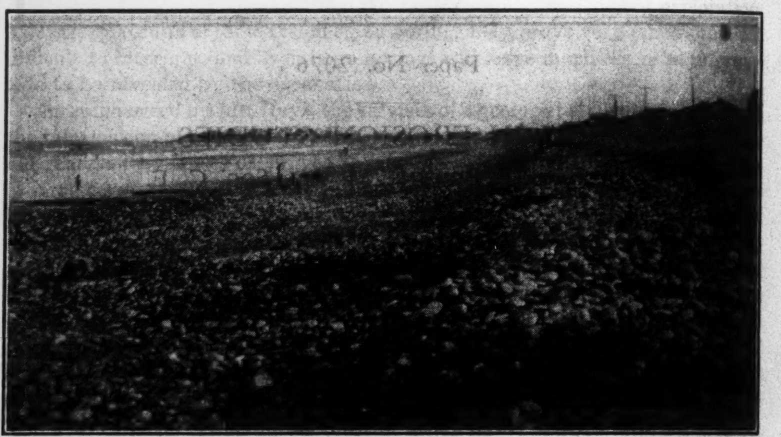

FIG. 1.—TYPICAL SHINGLE BEACH ALONG THE NEW HAMPSHIRE SHORE, NORTH OF BOAR'S HEAD

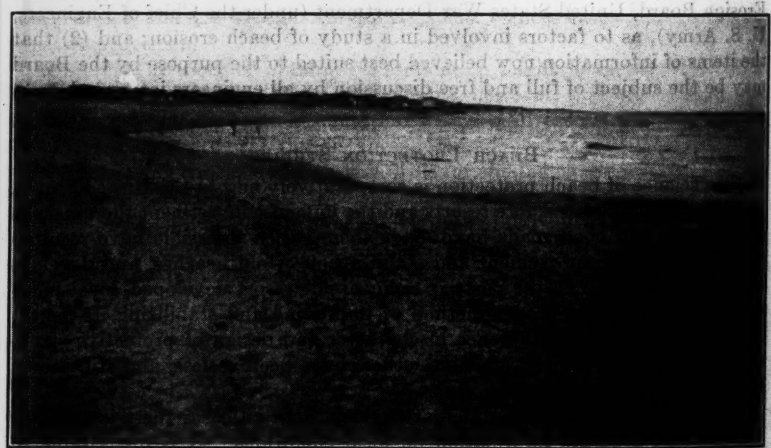

FIG. 2.—POCKET BEACH FORMED AGAINST A JETTY, AT HAMPTON BEACH SOUTH OF BOAR'S HEAD, N. H.

The Fifteenth International Congress of Navigation which met in Venice, Italy, in 1931, discussed the question of protection of coasts against the sea, and adopted a comprehensive report drawn up by its General Reporter for this subject, expressing its matured general conclusions. This report contains the following conclusions as to preliminary studies:

"Any plan for protecting coasts against the sea must be preceded by a careful study of the locality and all the factors acting in the formation of the coast, such as the nature and shape of the coast, and as to how much it is exposed; the action set up by waves, by currents of various kinds, by atmospherical water and by ice; the origin and nature of the materials constituting beaches; the flow of water courses which empty themselves onto the beaches and the regimen of the mouths of such water courses; the situation and regimen of the aquiferous sheets of fresh water flowing towards the sea; the influence of new constructions on the sea, when they project from the sea."

Characteristics of Beaches

The type of information required in a study is based on these general principles, and will depend for detail on the location of the area. Conditions vary somewhat for each location. The coastal area of the United States may be divided roughly into subdivisions in each of which general conditions are quite similar: North Atlantic, Central Atlantic, South Atlantic, Florida, Gulf of Mexico, South Pacific, North Pacific, and Great Lakes.

For purposes of beach erosion studies, the North Atlantic area may be considered as ending at Montauk Point, Long Island, N. Y., but including the north shore of Long Island Sound. The coast in this area consists of rocky or boulder-strewn headlands, and pocket or crescent beaches of sand or pebbles. Illustrative of these two types, Fig. 1 shows a steep shingle slope of the shore, with a narrow strip of sand at the water's edge; and Fig. 2 shows a pocket

Fig. 3.—Formation of Moriches Inlet, Long Island, N. Y., March 10, 1931

beach formed against a jetty. There are a few exceptions to this rule, such as at Salisbury Beach, and beaches along Cape Cod, in Massachusetts.

The south shore of Long Island, formed by the outwash of a terminal glacial moraine, with lagoon areas in the rear, is quite similar to the New Jersey shore and may be classed in the Central Atlantic area. This Central Atlantic type of beach (a comparatively narrow sandy barrier, broken at intervals by inlets communicating with lagoon areas in the rear) extends as far south as Cape Romain, in South Carolina. Fig. 3 is an aerial photograph of Moriches Inlet, Long Island, N. Y., as it was in the process of cutting through a sand barrier. South of this point, to the Florida line, the coast is intersected by innumerable tidal streams resulting in a chain of islands with sandy beaches on the ocean side and occasional marsh areas behind them. Still farther south lie the Florida beaches which superficially resemble those of New Jersey, but which, from the standpoint of beach erosion studies, are distinctly different because of a difference in climate and exposure to wave action, and the presence of limestone rock.

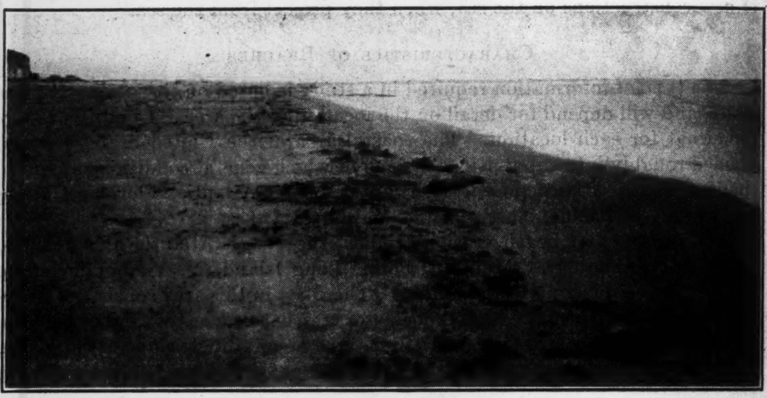

FIG. 4.—TYPICAL LOUISIANA BEACH; GRAND ISLE, LA.

The beaches along the Gulf of Mexico vary considerably among themselves. They are subjected to the same type of wind, weather, and wave conditions, and, therefore, are given a separate classification. From the southern tip of Florida northward there is the inaccessible and greatly intersected Everglade area, with a total absence of beaches. Northward from Naples, Fla., to Tarpon Springs, Fla., there are barrier islands with excellent sandy beaches. North of Tarpon Springs the shore is so well sheltered from wave action because of its location and the presence of shallow limestone ledges that mangrove swamps grow to the water's edge. This condition extends to Apalachee Bay, Florida. West of Apalachee Bay to the vicinity of the Mississippi River and from Sabine Pass, Tex., westward and southward to the Mexican border there are sandy barriers with good beaches, although the island barriers of the section east of the Mississippi Delta are so far offshore that each of the two parallel beach lines presents a set of problems of its own. This is particularly true of the mainland and island beaches of the Mississippi Sound area. In this vicinity the coast is broken by the low marshy islands of the delta, with some sandy beaches on the Gulf face. Fig. 4 shows a typical Louisiana beach on the Gulf side of a barrier island. The sand is very fine and both the foreshore and offshore are very flat. There are few dunes behind the water-line and the barrier is topped by hurricane tides.

For the purpose of beach erosion studies, the beaches in the South Pacific Ocean may be considered as those lying in the reach from Point Conception, Calif., southward to the Mexican border. The coast is comparatively young geologically, and the shores are narrow with comparatively high hills close to shore and deep water close offshore. This results in headlands between crescent beaches (see Fig. 5). The distance between headlands is comparatively great. Annual rainfall is light. During the rainy season, however, there are periods of heavy rain, the run-off from which carries sediment to the coast. This sediment forms much of the beach material.

North of Point Conception, in the North Pacific, the headlands become more frequent and the intervening beaches shorter. There is comparatively little sea-bathing in this area because of the coldness of the water, but the beaches are used as recreational areas during the summer months.

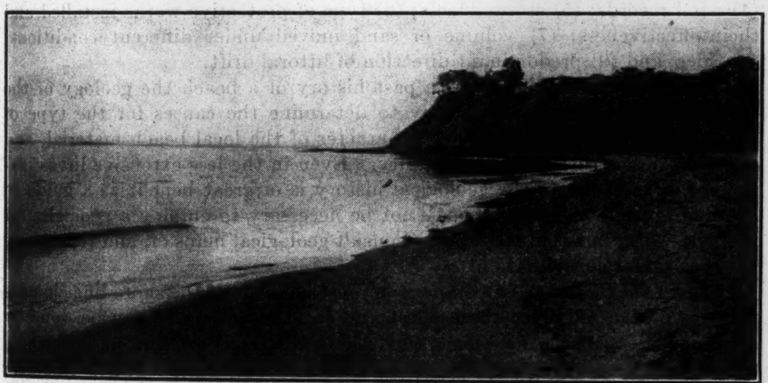

FIG. 5.—CABRILLO BEACH, SAN PEDRO, CALIF., FACING NORTH FROM THE BREAKWATER

The Great Lakes area offers a different set of conditions. The Lakes are tideless, but have seiches and seasonal variations in level. They are frozen near the shore during the winter and are subject to violent storms. The bottom materials, the fetch, the slope of the bottom, currents, and ice action, differ from those on the open ocean. The Lake beaches are generally composed of a layer of very fine sand over clay or mud. The offshore is flat, and some distance out from shore the bottom changes from sand to fine clay or mud. In some sections, such as the southern end of Lake Michigan around Chicago, Ill., there are extensive sand dune areas, but in most parts the Lake shores end against bluffs of clay of varying heights.

Scope of a Beach Erosion Study

Within each area local conditions will dictate to a large degree the extent of a study and the data required. Studies on a long unbroken beach will require different information from those in the vicinity of an inlet; and a study involving a highly developed resort, such as Atlantic City, N. J., would justify a much more searching investigation than a study of a similar area which is entirely undeveloped. In determining the data to be required, the location and the economic justification for the degree of detail are first considered.

The usual requirements for a beach erosion study are an investigation of the past history of the area from all available records, and an investigation of the present conditions by means of local surveys and observations. After this information is assembled a comparison with other similar areas where there are protective works is possible, and a proper design for the protection of the area under investigation can be made. With these requirements in mind, a brief description is given of information generally secured in a study, with the reasons for, and the method of, securing it.

There are nine principal items to be investigated in considering the past history of a beach: (1) Geology; (2) shore-line changes; (3) offshore changes; (4) wind records; (5) storm effects; (6) type of protective works installed and their effectiveness; (7) volume of sand moved under different conditions; (8) tides; and (9) predominant direction of littoral drift.

Geology.—In investigating the past history of a beach the geology of the area should be reviewed primarily to determine the causes for the type of coast encountered, the source and character of the local beach material, and the geological structure in the vicinity. Even in the less extensive investigations, a brief study of the geological history is of great benefit as a guide to the more recent history. It may not be necessary to employ a geologist for the field work, but it is desirable to consult geological maps of, and reports on, the area under consideration.

Shore-Line Changes.—A comparison must be made of the shore-line changes that have occurred since the earliest authentic maps. This can be done by studying all available field sheets of the United States Coast and Geodetic Survey, local surveys, and maps of surveys of the United States Engineer Department. These data are reduced to a common scale and the shore lines, both mean high water and mean low water, for all dates are plotted so that they may be superposed on one sheet. If sufficient surveys are available, covering a long period of time, a "good picture" is afforded of the progressive changes that have occurred. Along many parts of the New England and New Jersey coast excellent surveys have been made by the U. S. Coast and Geodetic Survey, extending back to 1839. Unfortunately, this is not true for all the seacoast. At some places the available surveys are irregularly or remotely spaced in point of time. For example, in a study at Daytona Beach, Fla., the earliest accurate survey that could be relied upon for shore-line changes was that of 1872–1874; the next one was made in 1928, a lapse of 54 yr. An office comparison of shore lines as outlined is made for all studies. Where a study warrants more detail, a survey showing the present location of mean high and low-water shore lines is made, and the results are superposed on a map of the old shore lines to show the changes to date.

Offshore Changes.—A history of offshore changes is secured in much the same way as that of shore-line changes. Copies of hydrographic field sheets of the offshore area, obtained from the U. S. Coast and Geodetic Survey and the U. S. Engineer Department, are reduced to a common scale and curves for 6-ft, 12-ft, and 18-ft depths superposed on one sheet for comparison. Where the changes between surveys are considerable, separate work sheets on a relatively large scale for each depth-curve comparison are prepared and then consolidated on one sheet for the report. In case of an extensive study, the 24-ft, 30-ft, 36-ft, 42-ft, and 48-ft curves are sometimes added. Generally, an offshore survey is required for the study in order to determine the present position of the curves to be compared.

The purpose of comparison of offshore depth curves is to determine if progressive changes are occurring. Past changes will have a bearing on probable changes to be expected along the shore in the future and will thus affect the design of proposed protective works. If the changes show a progressive and rapid movement shoreward of the depth curves, indicating a deepening of the offshore area, it is evident that severe wave action close to shore may be expected, which may cause increasingly rapid erosion of the beach. Conversely, a progressive shoaling of the offshore area will indicate a probable lessening of destructive wave action.

In studies of larger scope, it is desirable at times to study general trends on the bottom for distances of 5 to 10 miles offshore. This study is made from hydrographic field sheets of the U. S. Coast and Geodetic Survey. Ranges are selected along the area to be investigated on which soundings were made on several of the surveys. Composite profiles along these ranges are plotted for each survey and compared on each range. On the Atlantic Coast it has been possible, in several instances, to follow the seaward or shoreward trend of the depth curves to depths of 70 ft. On the California coast where depths increase rapidly offshore, there were bottom changes, in 300-ft depths, of as much as 18 ft between the 1869 and 1930 surveys. Such a large difference can scarcely be attributed to errors in soundings or movement of littoral drift, but may well have been caused by slipping or faulting during an earthquake. Investigation of this kind is most effective and profitable of results when done on a large scale.

Wind Records.—The next step in investigating the past history of an area is a collection of wind and weather records. There are three available sources for past weather records: The United States Weather Bureau, the Coast Guard Stations in the area under investigation, and airports. Generally, the nearest first-order station of the Weather Bureau can furnish quite accurate records since 1923. Prior to that time the instruments used were not standard and there is some doubt as to the accuracy of the records. Where the nearest Weather Bureau Station is some distance from the area under investigation it is well to take the records from the nearest Coast Guard Station. These generally consist of readings every four hours on the wind direction and velocity. The readings are approximate and must be reduced to a usable form for a study. This involves considerable office work, but affords a clear idea of general wind conditions in the area, particularly the duration and intensity of storms and of prevailing winds.

Some difficulty may be encountered in interpreting and using wind diagrams furnished by outside sources. Two types of wind-roses have been developed for beach erosion studies (see Fig. 6), which make it possible to determine the prevailing wind movement, the average velocities from each direction, and the direction of predominant storm winds. If, from an examination of the data, it is apparent that there is a great seasonal variation in wind direction and intensity, and if the detail of the study warrants, such wind-roses should be plotted for each month in the year over the entire period covered, and a second series should be made showing the average for each month, and, finally, the average for the entire period. Another source of wind information is the Hydrographic Office, U. S. Navy Department. Its records show prevailing winds and their intensities in 5° areas offshore as reported by ships.

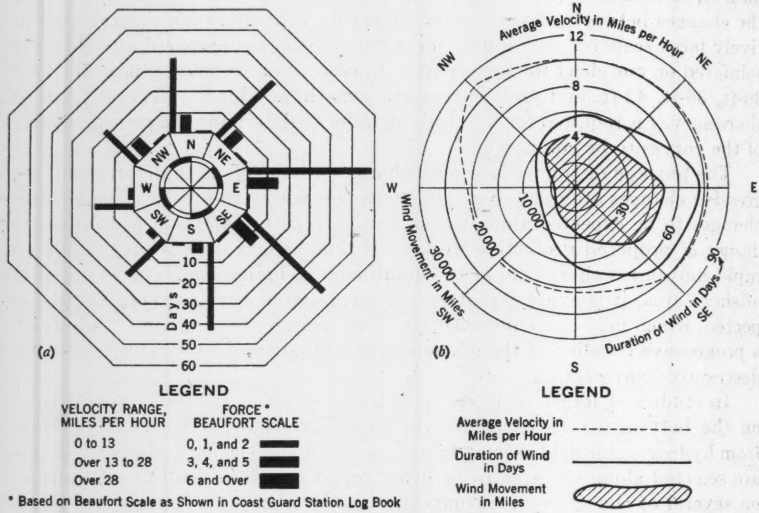

FIG. 6.—TYPICAL WIND DIAGRAMS

The study of past wind and weather conditions is important when correlated with the shore-line and offshore changes and reports of the effects of storms on the beach. By affecting the direction of wave approach, winds play an important part in determining the direction of predominant littoral sand movement. Wind-blown sand carried ashore plays an important rôle in dune building and lateral sand movement along the shore. By examining the history of winds and storms over a considerable number of years, it is possible to obtain some idea as to why certain changes have occurred and what to expect in the future, particularly with respect to sand movement, the direction, duration, and intensity of storms, and the time of year when storms may be expected. The extent to which the investigation of wind and weather is carried will be determined by the general detail warranted for the study. It should not be ignored in any study.

Storm Effects.—In addition to the study of winds, a history of the general effect of intense storms in the area has been found of value. The information may be obtained from long-time residents, from newspapers and other records, and from photographs. Particularly desirable is the extent of erosion or accretion caused, the apparent effect of any protective works or other structures in the area, and the height to which the tides rose during storms. Since there is danger of exaggeration, in any eye-witness description of storm action, such description must not be relied upon too heavily. Photographs showing conditions before and after a storm are among the most reliable sources of information.

Existing Protective Works.—In the history of a beach area, a complete and accurate record of any protective works which have been installed must be secured. This should cover the location, profile, and date of construction of each, with a history of its effect upon the beach and its length of life. It is usually possible to get the plans and specifications if the structures were built by a municipality, State agency, or the Federal Government. In all cases, it is possible to note the present condition, the effect on the beach, and the probable life. Where long structures such as jetties have been in place a considerable period of time, changes in the offshore areas as well as those at the shore line should be considered.

In a detailed study, the effect of all structures projecting into the sea on the shore line over a number of years should be followed. Changes in the location of the shore line and the depth curves are valuable indications. Frequent or yearly hydrographic surveys should be available with sounding ranges fairly close together and profiles extended back from these ranges over the area of dune sand. From such surveys it is possible, by using a similar grid for each year, to compute the volumetric sand changes in the shore and offshore area to the limit of the surveys. This is being done at several places along the Atlantic Coast with very interesting results.

In evaluating the effect of groins or jetties it is necessary to discriminate between the effects of a single structure and that of a system. The supply of sand that may be trapped along a given shore may have been sufficient to show satisfactory results with a single structure, but may not suffice for prompt results for a system of structures. An artificial supply of sand may be required in such a case.

Tidal Data.—It is advisable to learn about the tides in the area under investigation. The time and height of tides, the mean range, and spring and neap ranges may be obtained from tide tables published by the U. S. Coast and Geodetic Survey. In addition to these mean values, it is important to secure information on the extremes under storm conditions, since any design of protective works must consider these extremes. This information can be obtained from the U. S. Coast and Geodetic Survey for points where tide gages have been established. In other cases it is necessary to refer to the U. S. Coast Guard or other local records.

There are no tides on the Great Lakes but there are minor irregular variations in level known as seiches and fairly regular seasonal variations between winter and summer, averaging between 1 ft and 2 ft. During the winter the Lake levels are low and during spring and summer they are high. In addition to the seasonal variations there are long-time cycles of higher waters and lower waters. In the case of Lake Huron, for example, the seasonal variation since 1860 averages 1.2 ft, the cycle of higher waters averages 14 yr and the maximum difference between higher high waters and lower low waters has been 6.30 ft. It is apparent that variations of this nature must be considered in designing any protective works on the Lakes. The United States Lake Survey has kept accurate records of seasonal variations in all the Lakes since 1860.

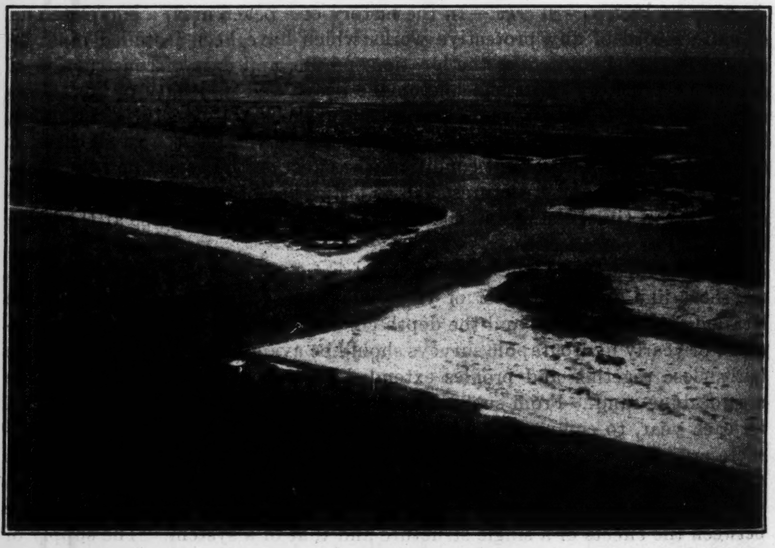

Fig. 7.—A Typical Florida Beach; Lake Worth Inlet, Fla.

Littoral Drift.—The last item to be considered under the past history of an area is the direction of predominant littoral drift. This information is most important in the design of a protective system. From the shore-line changes, particularly near an inlet or jetty, and from changes in offshore depths, the direction of preponderant movement of the littorally drifting sand may be determined. The direction of growth of a point, the migration of an unimproved inlet, or the accretion on one side of a jetty, will give good evidence of the direction of predominant sand movement. In Fig. 7, for example, littoral drifting sand is piled against one side of a jetty entrance to the detriment of the beach on the leeward side. Inferences from an accumulation of sand against either side of a short groin at any particular time of year may be erroneous since, at many places, there are seasonal reversals of the direction of sand movement. The direction of wind and of wave approach plays an important rôle in directing sand movement along the shore and in seasonal reversals. If the detail of the study permits, observations as to the direction of littoral drift should be continued over a period of a year to determine these seasonal changes.

Comment.—In a beach erosion study, the foregoing nine items dealing with the history of the beach are all considered. This is relatively expensive, since considerable office work is involved. Caution is given against singling out one of the items of investigation and basing conclusions and recommendations on it. For example, the history of offshore changes may show a considerable movement seaward of the curves for 6-ft, 12-ft, and 18-ft depths indicating shoaling of the offshore area. Normally this would afford greater protection to the beach. However, there might be a near-by longshore channel with comparatively high current velocities which could cause a serious erosion of the beach. In all studies it is important to complete all the items of investigation, to correlate them, and to give due consideration to their accuracy before arriving at conclusions and prescribing a remedy.

FIELD WORK

After having decided upon the items involving historical phases of the study, a plan of field work should be drawn up to ascertain present conditions. The location of the beach, the problem to be solved, and the availability of funds will dictate what field work should be included.

Eleven major items of field work must generally be considered, many of them being closely related and all of them involving varying degrees of detail, namely: (1) Character of the beach; (2) character of the offshore area; (3) currents; (4) tidal prism of inlets; (5) tides during the field work; (6) littoral movement of sand; (7) present condition of protective and other works, and their apparent effectiveness; (8) wave direction, velocity, and height during current and sand movement observations; (9) wind conditions during the course of field observations; (10) sand analyses; and (11) periodic aerial photographs.

Character of Beach.—The usual procedure for small studies, in determining the characteristics of the beach, is to measure profiles extending across the dune line to wading depths beyond mean low water. These profiles are spaced from 200 to 500 ft apart along the entire front under investigation and are perpendicular to the shore. When plotted they furnish information on the height of dunes, the general slope and shape of the area above high water, the location of mean high-water and mean low-water lines, and the slope of the foreshore. These are all factors in the design of protective works and should be included in all studies. Sand samples are taken at the mid-tide elevation on the beach at each profile. These samples are analyzed for median diameter, specific gravity, porosity, and shell content. Since the degree of wetness of beach sand greatly affects its physical properties, a determination of its moisture content, and of the source of the water, whether the sea or ground-water, is coming to be considered a matter of some importance.

There is a possibility of a relationship between the slope of a beach and the characteristics of the sand composing it. In general, it appears that the greater the median diameter the steeper will be the beach slope; and the smaller and more uniformly graded the sand, the flatter the slope will be. Although it is not of great importance to any particular study this information may be included for statistical purposes.

The analyses of the sand are of value in determining the source of supply of the beach sand. Where this is of material interest to the study, samples are secured from all suspected sources for comparison with the beach samples. Complete petrographic studies are usually made only in special cases.

In the case of extensive and detailed studies, topographic maps of the area should be made to show dune location and height, and the character of the country some distance landward of the beach. Aerial photographs are useful in connection with these maps to show the extent of developed areas and buildings.

Character of Offshore Area.—The under-water topography can be obtained from a general hydrographic survey of the area or by extending the shore profiles to depths of 18 ft to 30 ft below mean low water. For smaller studies it is usually not necessary to extend these lines beyond 1 500 ft from shore, or to more than a depth of 18 ft below mean low water. These profiles or hydrographic surveys are important in any study to show the offshore slopes, and the presence of offshore bars and reefs, and to afford a comparison of present conditions with those shown in previous surveys. The existence of an offshore bar or reef, if close to shore, will affect the design of groins.

In more detailed studies it is necessary not only to know the under-water topography, but also the character of the bottom materials, since the bottom may be the immediate source of material reaching the beach. Bottom samples should be dredged on the intersections of a grid system and then mechanically analyzed and leached with hydrochloric acid. The results will show the character of bottom material and shell content of the samples. Borings may be used, if desired.

In cases involving inlets the system of profiles is usually not sufficient because, in addition to the profiles, it is desirable to have a sufficiently detailed hydrographic survey of the inlet to develop the entire outer bar, the inlet channel, and the inner bar.

Currents.—A study of currents in the ocean comparatively close to shore is of importance in determining the direction of sand movement along the beach and bottom. In measuring currents offshore, it has been found convenient to use floats covering a complete tidal cycle, to determine any changes caused by difference in the phase of tide. Except immediately adjacent to the shore, and at inlets, such currents are usually moderate or slow.

At the same time that the offshore currents are being measured by means of sub-surface floats, the currents on the same lines close to shore should be measured. From the limit of wave up-rush to wading depths this can be done conveniently by timing the longshore movement of the water by surface floats or by the use of colored liquid. The latter is preferable since it registers the actual movement of the water through the wave up-rush and back-wash and is not affected by wind. Potassium permanganate or washing blueing have been satisfactory for this work. The measurements of current near the shore must continue over the entire time during which the offshore currents are being measured—one full tidal cycle.

For more detailed studies warranting a close determination of the bottom currents a specially designed current meter[2] has been developed which can be operated at any reasonable depth from a boat offshore. These meters are very satisfactory and are much to be preferred to sub-surface floats since they register the actual bottom currents—those that move the sand. Measurements must be made at a reasonable number of points along each range line to be covered, and, at each point, must cover a complete tidal cycle.

In offshore current work, with the present equipment, it is impracticable to make measurements except during fairly calm conditions. It would be a decided advantage to know the relation between calm-weather currents and sand movement offshore and those prevailing during storms, and also the depth in which sand movement occurs during storms.

Tidal Prism of Inlets.—If the study involves the fixation or improvement of a tidal inlet, additional current measurements of a somewhat different type are required. A careful cross-section of the gorge is made and currents are measured at sufficient points along its line to enable making an accurate computation of the tidal prism. This requires that the measurements at each point extend over a complete tidal cycle. A tide-gage should be established at the ocean entrance to the inlet and another at the lagoon end. Where staff-gages are used they should be read every 15 min during the period of current measurements. If the study warrants, staff-gages should be established and read at critical points in the rear areas of the lagoon to determine the propagation of the tidal wave in the lagoon. Since the currents in the inlet are tidal and persist longer than oscillations due to wave action, any good type of current meter will be found satisfactory. The data are used, and conclusions drawn therefrom, as described by the writer in a paper published in 1928.[3]

Tidal Data.—Many of the items of field work are closely related to others. One of these items is the securing of accurate tidal data. The times of high and low waters and the average ranges of mean tides and spring tides, as given in tide tables, cannot be used for the reduction of soundings made along profile lines in the ocean, nor for correlation with the current measurements. They are means of long-time observations. Wind and weather have such an effect that the actual tide rarely, if ever, follows exactly the mean, as given in the tables. Therefore, whenever a study involves ocean profiles, ocean currents, a study of sand in suspension, or of inlets, it is important to establish a tide-gage to register ocean tides at the area under investigation. These observations must be made continuously during the time of field work.

Littoral Drift.—Direction of sand movement is determined, if possible, from historical evidence. It should also be studied in the field. If the importance of the study warrants it, a field determination of the volume of sand movement in the water under calm-weather conditions at the time of the study may be made with a fair degree of accuracy. This is done at the same time and on the same lines as the current measurements. Samples of water with the sand in suspension are taken from the bottom upward to a point where there is none. Fig. 8 shows a deep-water sampler in a partly open position. If currents are being measured by means of sub-surface floats, the boat releasing the floats takes several samples at each point and additional samples each time the floats are set on the range. Samples are taken in 1-ft increments above the bottom point until no sand is noted in the sample. This process must be continued throughout the full tidal cycle as in the case with the current measurements. If bottom currents are being measured with the current meters, samples are taken periodically throughout the time of meter readings at each station. The samples of sand in suspension should be secured for each line upon which currents are being measured.

FIG. 9.—HAND SAMPLER

In addition to the aforementioned offshore samples, samples to show percentage of sand in suspension must be secured from the limit of wave up-rush to the limit of wading depths on the same lines and covering the same period as the offshore samples. A hand sampler, similar in general principle to the offshore sampler, is used for this work (see Fig. 9).

The sand is filtered from all samples on the site and sent to a laboratory where the percentage of sand in suspension is determined. From the results thus obtained, curves showing the average percentage of sand in suspension at each point and the upper limit of suspended sand may be plotted. These data, combined with the results of the current measurements, permit rough computations of the volume of sand in suspension moving across a given line perpendicular to the beach from the limit of up-rush to the profiles. This method necessarily neglects the sand that is moving along the bottom by saltation, but there will be no such movement unless the current velocity is greater than the critical. As in the case of the current measurements it is impracticable to secure these samples except under fairly calm conditions, and, therefore, no comparison has been made between sand movement during normal and storm conditions. The investigation of the Beach Erosion Board of this sand movement thus far indicates that during calm weather approximately 80% of the sand movement is in depths of water less than 6 ft.

On many beaches the movement of sand by the wind may be of importance. Offshore winds have little dry sand-moving capacity, but winds on shore or parallel with it may move it in large volumes. Observation has shown that dry sand is not moved by wind having a velocity less than 11 to 12 miles per hr, but above that rate movement increases rapidly with wind velocity. The rate of wind-blown sand movement, when desired, may be measured in a suitably designed trap.

Observation of Protective Works.—In order to determine the effectiveness of protective works a close examination should be made to compare their present condition with the plans and specifications. It is well to check whether they were built in accordance with the specifications or modified. Careful notes should be made as to the spacing, length, and height of groins, and the apparent effect on the beach of these factors. Photographs of the beach for some distance on either side of the protective works are of value in formulating conclusions and in planning new protective works. Especial care should be taken to observe the effects of existing protective works which project from the coast line.

Wave Data.—Whenever observations on currents in the ocean or sand in suspension are made, careful readings of wave data should be made and recorded. The following data should be observed and recorded both for the shore and offshore stations: Wave height, period, length, velocity, and direction of approach. Accurate determination of these five factors is difficult, but a close approximation may be made by observing and averaging ten waves at intervals of 15 to 30 min. Offshore the wave height may be measured by observing the rise and fall on a lead line held with the lead just resting on the bottom. The period may be clocked, of course, and the velocity timed from bow to stern of an anchored boat. The length may be computed from the period and velocity, and the direction of approach read by compass. Near the shore the measurements are easily obtained if there is a pier close by. If no pier is available, piles may be driven at known intervals perpendicular to shore. This is comparatively expensive and is not warranted in a small study. Wave height, direction of approach, and period, which are the most important factors, can always be read from shore without the pier or piles.

Waves are a most active agency in moving sand along the beach. The data obtained from the aforementioned observations should be scrutinized carefully in conjunction with the currents, the sand in suspension, and the wind and weather conditions for some time prior to the observations. An examination of the wind-rose and the history of direction of predominant sand movement correlated with the wave data, currents, and sand in suspension, will assist in forming an opinion of the erosive forces and in designing a system of protective works.

Wind Data.—As accurate a record as possible should be kept of the wind direction and intensity during the course of the field work. The cost of this item is small, and it is useful in determining the effect of wind on the direction and characteristics of the waves.

Sand Analyses.—In the design of a bulkhead or groin, or for the dredging of a channel through a spit or outside bar, it is important to know the character of the sub-surface materials. In the normal beach-erosion study it is only necessary to know whether there is any rock or hard material that will make the driving of piles difficult or impossible. This information may be obtained by probing or by jetting if the piles are to extend to a considerable depth. To secure a more accurate idea of the character of the material, test pits above the high-water line may be dug at intervals along the beach and a log made of the materials.

To determine the character of the offshore sub-surface, wash borings may be made below the bottom from the shore out to depths of 40 ft, or more, below mean low water.

Aerial Photographs.—Fig. 10, a view of Moriches Inlet, Long Island, may be compared with Fig. 3, taken one month earlier. In Fig. 3, the rapid on-rush of water from the bays in the rear shows the inlet in process of forming. Fig. 10 shows the effect of tide action in forming a beautiful delta inside the inlet. Such aerial photographs are excellent for a continuing study, such as when it is desired to follow and record progressive changes like the migration of an unimproved inlet on a sandy coast, or the effect of accretion or erosion near jetties. For any study, they have an advantage in showing the general character of the shore. Unless they are already available the cost of securing them is prohibitive for a small study. Through the co-operation of the United States Army Air Corps, the Coast and Geodetic Survey, and the Geological Survey, the Beach Erosion Board listed the areas of the coast that have been photographed.

Comment.—In outlining the field work for a beach erosion study, all the items mentioned should be considered and evaluated with regard to the particular problem to be solved and to the extent of detail justified by the funds available. Some items may be eliminated and others may be greatly curtailed. In this case as in many other engineering problems, the experience of the investigator and his judgment play an important part since it is impossible to prescribe fixed rules. One general rule may be given: An engineer laying out a beach erosion study must not allow his desire for quick results to curtail the work necessary to secure sufficient data upon which to base a plan of protection.

After the data decided upon have been secured, each item should be developed separately and then correlated with the others to obtain a true picture of the forces at work and their effect. The wind-roses should be examined carefully and compared with the wave data to determine the possible effect of the winds upon the height and direction of approach of the waves. Study the current measurements, the sand in suspension, and the tides, to note the respective effects on heights and time. The long-time wind-rose should be studied in connection with the history of beach and offshore changes and the effect of storm action. From past beach changes as effected by past weather conditions and past storms an idea may be formed as to the future changes to be expected.

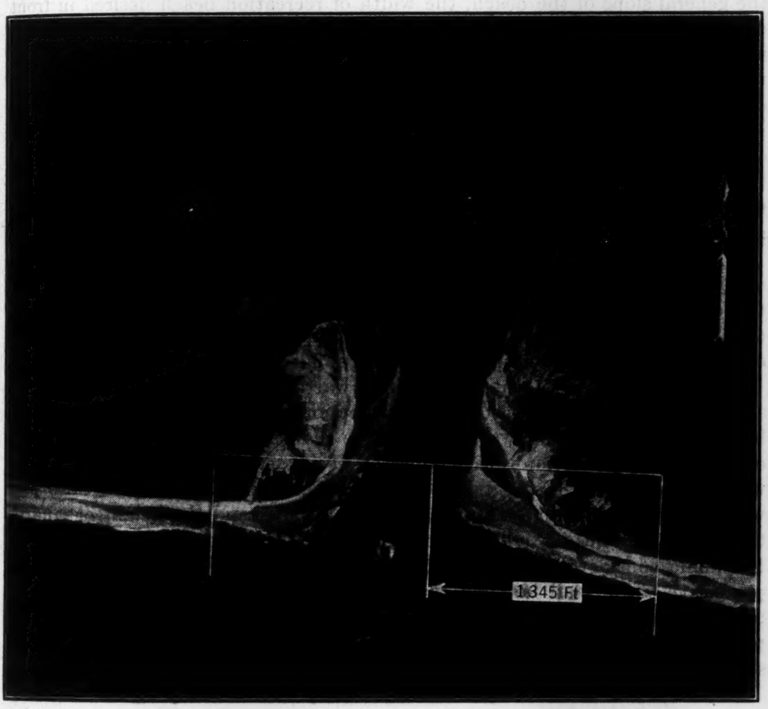

FIG. 10.—MORICHES INLET, LONG ISLAND, N. Y., SHOWING DELTA FORMED BY ONE MONTH OF TIDE ACTION

OBSERVATIONS ON DESIGN OF PROTECTIVE WORKS

Bulkheads.—The problems to be considered in preparing a design for a simple bulkhead and groin system may be summarized briefly. Assume the case of an area to be protected on a long straight stretch of beach distant from the influence of an inlet or change in direction of the shore. Assume that the solution may call for both bulkhead and groins. First, consider the placing of a bulkhead. The factors governing this problem are the location and character of the developed area in the rear, the presence or absence of dunes, the general slope of the beach, the width of recreation beach desired in front of the bulkhead, the character of wave action, and the character of the subsurface material. This information can be obtained from the topographic map or the profiles, the wave observations, history of storms, and the probings or borings.

The line of the bulkhead should be kept as straight as possible. Where slight changes in direction of the beach require a change in direction of the bulkhead, this should be accomplished by a gradual smooth curve, not by sharp angles. Sharp angles or set-backs in a bulkhead system generally cause a concentration of the wave forces with resulting erosion.

Determination of the proper height for a bulkhead requires the consideration of four factors: (1) The character and extent of the development in the area to be protected; (2) the elevation and character of the ground in the rear; (3) the maximum heights and frequency of storm tides; and (4) the probable effect of the groin system in accumulating sand.

Where the development is extensive, warranting the expenditure of considerable sums to afford complete protection against over-topping by the highest storm tides and waves, a massive sea-wall is suitable. An example of this type of protection is the Galveston (Tex.) sea-wall. At other locations, with extensive developments, due to the character of the storm tides and wave action, the volume of sand on the foreshore, and the height of land in the rear, a bulkhead would answer the purpose at a considerably lower cost. Economic considerations determine whether the height and strength of the protective work shall be such as to afford complete protection or whether protection should be afforded against ordinary storm tides only. The lesser protection against ordinary storm tides and waves may result in some destruction during exceptional storms but will prevent complete disaster.

Assume that the development warranted protection only against ordinary storm tides, and that the land in the rear was comparatively low. In determining the proper bulkhead height the probable effect of the groin system in accumulating sand to act as a buffer to storm waves should be considered. If a large quantity of sand is moving along the shore, to be trapped by the groins, this accumulation will act as a buffer to trip the storm waves and prevent their breaking over the bulkhead. The average frequency, duration, and direction of storms should be studied to determine whether one storm might be expected to remove all the sand accumulated during normal conditions, and whether recurrence of storm conditions might be expected before normal conditions have restored a sand supply between the groins. Where conditions are bad, the sand supply cannot be counted upon to act as a buffer to the storm waves, and the top of the bulkhead should be placed at an elevation equal to the average height of the highest yearly storm tides plus wave heights, omitting from consideration extremely infrequent hurricane tides. If the sand accumulation can be counted on to trip the waves before they reach the bulkhead, the bulkhead height may be reduced by the average wave height.

The details of design of the bulkhead will depend upon the character of the sub-surface material and on the probability of the bulkhead being subjected to the direct force of the breaking wave. The length of piles should be such that they will have about two-thirds penetration when the beach is cut down to the point where the low water is at the foot of the wall. Piles should be tied back so as to insure against failure by pressure on the land side when exposed to low water on the ocean side and should be braced to resist wave action on the ocean face. It is important in the design to insure imperviousness to protect the back-fill. The leaching of the back-fill through a bulkhead is a common cause of failure. Consideration should be given to providing release for the water topping the bulkhead during storms so that property in the rear is not damaged.

Where groins may be expected to trap sand to form a beach, the bulkhead is simply a last line of defense and an insurance against serious property loss during exceptional storms. Where the land in the rear is fairly high and well consolidated, the average storm action is not severe, and there is a sufficient volume of littoral drift to insure filling the groins, the bulkhead may be omitted. The groins should then be well keyed back into the high land in the rear. In omitting the bulkhead, it must be realized that since there is no insurance against damage by flanking, immediate and costly repairs may become necessary.

FIG. 11.—TYPICAL GROIN

Groins.—In the design of a groin the profile should be based as nearly as possible on maintaining or restoring natural conditions (see Fig. 11). An examination of profiles of beaches measured after a considerable period of normal conditions shows, in general, a flat horizontal berm above the high-water line; then there is a sloped section extending from this upper berm to a point below low-water line; and, finally, a more gentle under-water slope. The profile should follow these variations with modifications made necessary by the difficulty of construction in the ocean. Fig. 11 shows an inner horizontal section, a connecting slope, and an outer horizontal section.

The inner horizontal section must be securely fastened to the bulkhead or must be well keyed into the high land in the rear. The top of this inner section is at the average elevation of the natural berm over the entire area to be protected. The length of this horizontal inner section is determined by the requirement of providing an adequate recreation area for the number of people expected to use the beach. Here, economics influences the "picture." If the demand is for a wider upper beach or berm than may be expected from natural accumulation, the groins may be filled artificially by sand pumped from areas in the rear or from the sea offshore. Sometimes, sand is transported from a selected source.

The angle of slope of the intermediate section is made slightly less than the average natural slope of the beach in order to encourage as flat a beach as possible. Since this section joins the inner and outer horizontal sections its length will be fixed by its slope and the difference in elevation between the two horizontal sections.

The top of the outer section is usually fixed at the elevation of mean sea level. This is a compromise with the ocean forces and the difficulties of construction. As far as the ocean forces are concerned it would be well to keep the top of the outer section of the groin below mean low water in order to check the wave currents, but not to oppose directly the force of the wave above the still-water level where its maximum force is exerted. The practical difficulty of construction below the low-water line in the ocean makes this uneconomical. Several experimental groins at Palm Beach, Fla., constructed in 1936, have alternate piles driven to mean low water with the top of the others at mean high water.

The length of the outer horizontal section of the groin will depend on the offshore conditions. If there is a reef or fairly permanent offshore bar within a reasonable distance of shore, the groin should extend across the longshore channel inside the reef or bar and end on the crest of the reef or on the outer face of the bar in depths of about 6 ft. If the offshore slope is fairly uniform the groin is usually extended to depths of 6 ft below mean low water. If the sand supply moving along shore is large enough to indicate a decided accretion between the groins and a material movement seaward of the normal low-water line this depth may be exceeded. Since about 80% of the littoral drift under normal weather conditions occurs shoreward of the 6-ft depth curve, and since observation shows a depth of about 6 ft at the ends of many successful groins, the 6-ft contour has been selected as the proper location for the end of the groins.

The detail of design of the groin will depend on the exposure to wave action and on the material used. Groins should be made sand tight with sheet-piles well bound together by wales and supported by long piles to resist the wave action against them. The sheet-piles should have approximately two-thirds penetration under the most severe erosion expected to occur. In some locations it was unnecessary to use long supporting piles but their omission is not recommended unless good penetration in hard material affords a natural anchorage below which erosion cannot go.

In determining the spacing between groins there is a general rule, obtained from many observations of groin system: The ratio between the length of groin and the distance to the next groin should be between 1 to 1 and 1 to 3. Spacing closer than 1 to 1 does not injure the beach, but is never economical. Spacing greater than 1 to 3 appears to be ineffective in holding a good beach. Within these limits the spacing is determined by the direction of approach of the storms causing the most severe erosion on the beach. After the length of groin has been fixed by offshore conditions, draw a line through the end of the groin parallel with the direction of the storm approach. The projection of this line on the line of the bulkhead will determine the proper space to be allowed between groins. The spacing thus determined, of course, will not always fall within the limits previously set. If not, the nearest limit should be used. This method of determining spacing is not so haphazard as it may seem from a brief description. The more directly onshore the wave action is, the less will be the littoral movement of sand under the influence of the wave forces, and the less serious the erosion. In the case of storm action parallel to the coast the resulting waves do not travel parallel, but the shoreward ends are retarded so that the wave reaches the shore at an angle of about 16 degrees.

The bulkhead must be protected securely at each end against flanking by providing substantial wing-walls into solid land. The danger of increased, or of continued, erosion beyond protective works must be recognized. Numerous methods have been tried both in Europe and in the United States to prevent this cutting back beyond the ends of protective systems. In some cases a progressive reduction in length of groins toward the ends has proved successful whereas in other cases it has not been effective at all. Normally, the greatest erosion occurs at the end of the system away from the direction of sand drift. In some of its designs of protective works, where the littoral sand movement is small or where immediate results are desired, without waiting for slow natural accumulation, an artificial supply of sand can be provided to the beach by dredging from the open sea, or from near-by sheltered waters, if available, or by other means, if required. In many cases dredging offers a quick and inexpensive method of compensating for the normal losses of sand from beaches. Artificial supplies of sand must be renewed from time to time, but the method is worthy of consideration in preparing most designs.

CONCLUSION

Considerable research and study remain to be done before the problem of beach protection can be reduced to a definite science. There is further need for experiments in the ocean on currents, waves, and sand movement; by model experiments in its wave tank; by investigation of materials used in protective works; by periodic aerial photographs of certain areas; and by continued examination of the effect of existing structures.

DISCUSSION

Morris N. Lipp,[4] **M. Am. Soc. C. E.** (by letter).—The mention, in this discussion, of certain phases of the beach erosion problem which Colonel Brown did not set forth in his comprehensive paper, is not intended as a criticism of his failure to discuss these matters. They are presented in accordance with his request that his paper be the subject of full and free discussion by all interested engineers.

With full realization of the correctness of his assertion that every locality presents a different problem, a discussion should essentially be confined within the limits of an engineer's own experiences and observations, in order that an accumulation of discussions will establish some definite fundamentals. It is first necessary to know why certain problems exist, whether they are Man made or Nature made. If caused by the activities of Man, the engineer in charge of such activities should be fully cognizant of the future problems that are created.

Two of the factors that contribute to the problem of beach protection are the desire to erect buildings on ocean-front property, and the construction of inlets for sanitation and navigation. It is not within the province of the civil engineer to protest these desirable and necessary activities when kept within reasonable limits, but it is his duty to help solve the problems they produce.

Colonel Brown cites the necessity for geological studies and establishes vital points in his discussion of littoral drift. Once the direction of drift is determined an important barrier is hurdled. It is now accepted as true that the general movement of sand along the Florida east coast is in a southerly direction. This principle was established by the Florida State Geological Division. Analyzing sand at various points along the coast, and tracing the sand to its source of supply, entered into its studies. The engineer, as Colonel Brown points out, sees evidence of the direction of drift at jetties.

At inlet jetties on the Florida east coast there is accretion to the north and erosion to the south. In certain instances sand tending to pass by an inlet is carried from the ocean through the inlet and deposited in the bay to the rear. This latter phenomenon tends to destroy the purpose for which the inlet was constructed. An attempt toward the solution of the beach erosion problem in the vicinity of an inlet has been attempted at the Boynton Inlet, where the sand is pumped from the north side to a system of protective works on the south side. Conditions to the south have been considerably improved since pumping began. No doubt general practice of this kind will provoke objections from property owners on the north side of the inlet. In certain instances it may be feasible to pump sand that has drifted from the ocean into the bay back into the ocean to the south of the inlet.

It should be emphasized that in many instances a beach erosion problem would not exist had inlets not been constructed. Therefore, serious consideration must be given by the civil engineer, during the design of an inlet, to its ultimate effects on adjacent property.

---

[4] City Engr., Miami Beach, Fla.

Colonel Brown states that the progressive reduction in length of groins toward the ends of a protective system has proved successful in some instances, whereas in other cases it has not been effective at all. In South Florida attempts have been made toward progressive reduction, but they have not been successful. It should be realized that after a system of protective works has been constructed on the east coast of Florida its extension to the south will be required eventually.

The requirement advocated by Colonel Brown that a groin be sand tight is correct. This type has proved to be the most successful in Florida. Permeable groins have been constructed, but there have been instances in which they have been converted to solid ones.

To adopt a ratio between the length of the groin and spacing of 1 to 3, which is one limit of Colonel Brown's suggested spacing, would be a radical change from the ratio now used in southeast Florida where an economical length of groin is approximately two-thirds of the spacing.

The length of a groin plays a large part in the extent to which a beach will build up. At Miami Beach, where approximately 9 000 ft of ocean front are protected by city-constructed works, groins in one system have a length of 170 ft, in a second a length of 200 ft, and in a third a length of 250 ft. More extensive lengths of beach have been built up in the areas having longer groins. In all these systems the two-thirds rule has been followed. Naturally, in many instances, such considerations as depth of water, wave action, and structural stability will determine the length.

Other factors such as wave height and life of the structure should be considered, in addition to those mentioned by the author, to determine the profile of a groin. The inshore end of a groin should be above normal wave height, not only because it is desirable to have an available beach at high tides, but so that such a beach will be formed that ordinary waves will break on it, and not against the bulkhead. The back-lash of waves breaking against a sea-wall and meeting the incoming waves will not only retard the building up of a beach, but may prevent the making of one. Where it is desired that the beach be made naturally, it would not be necessary to construct the inshore groin elevation above a point where occasional heavy storms would deposit sand.

Because of the expense involved in protecting beaches it is necessary, as Colonel Brown states, to study the history of existing protective works. In Florida, problems of deterioration and structural stability enter into the economics of groin design. In localities such as Palm Beach, where there is a strong surf, steel-piling has been badly eroded by sand action. At Miami Beach, where there is comparatively light surf, there are only a few signs of steel erosion. When difficulties of this kind are anticipated creosoted timber sheeting, so designed that it can be renewed readily, should partly encase the steel groins. Corrosion of steel in groins appears to be of minor importance. The sand covering at the inshore end, and the continuous wetting and accumulation of barnacles on the outer end, are factors that retard corrosion.

In southern waters, toredo attack creosoted timber through field cuts and drill holes. The life of creosoted timber can be increased by requiring all cutting and drilling to be done before treatment. Special care during construction has proved this method to be feasible. At Miami Beach, where there is a 2.5 ft mean tidal range, steel groins braced by creosoted timber wales and piles have been built at such an elevation, in some instances, that normal water does not touch the timber wales. Groins of this design, with an inshore elevation of 6.5 ft and an offshore elevation of 3.5 ft above mean low water, have functioned successfully.

The forming of deep water at the end of a groin, by eddies, makes special attention necessary for structural stability. Longer sheet-piles and heavier braces are advisable in the affected areas. The placing of granite blocks, if such blocks are available at a reasonable cost, should be effective in strengthening the ends.

Colonel Brown sets forth four important factors that should be given consideration in determining the proper height for a bulkhead. The problem of determining the height of a bulkhead has been comparatively simple at Miami Beach. The top coincides approximately with the backshore terrace. The top elevation is 8.5 ft above mean low water, which is above the ocean water at all times except during severe hurricane periods. To build a bulkhead to hold back hurricane seas would not only be unjustifiable economically, but would impair the appearance of the beach and the view of the ocean.

At Palm Beach the problem is more difficult. In that town there is a highway along the backshore terrace at 16 ft above mean low water. Generally the bulkhead has been constructed close to the highway at approximately the elevation of the highway. In 1937, a bulkhead was constructed to the seaward of the customary location, at an elevation of about 9 ft above mean low water. Naturally, this method of construction is cheaper than the usual type. The height is sufficient to withstand ordinary seas. There is not only an expansive beach in front, built up by the groins, but there is also considerable sand space between the bulkhead and the highway. During hurricane seas there would possibly be some erosion to the rear of the bulkhead. However, if the slope of the sand between the bulkhead and the highway were constructed at a grade not much steeper than the slope of the beach seaward from the bulkhead the tendency toward erosion could be diminished. By virtue of the economies involved and the additional available beach space, construction of this type is worthy of special attention and study.

Corrosion of a steel piling bulkhead does not appear to present a serious problem as only the exposed portions are affected. Since the exposed portions are of shallow depth in a well-designed system an inexpensive concrete cap can be placed to replace a corroded portion.

Colonel Brown has made an excellent contribution to the science of beach protection and his excellent paper deserves a place in the library of every interested civil engineer.

George A. Soper,[5] M. Am. Soc. C. E. (by letter).—Engineers will be indebted to the author for setting forth with such admirable clearness the resources which have been developed by the Beach Erosion Board for the investigation of beach erosion problems along the sandy coasts of the United States, and for the recommendations he has made for the construction of bulkheads and groins.

---

[5] Cons. Engr., New York, N. Y.

The point of view of the engineer who is called upon to protect a piece of property is not always one which is favorable to exhaustive investigation. He must be satisfied with what is necessary and sufficient; for the engineer has a specific, and usually a limited and pressing, problem that he must solve, and he must solve it at the least expenditure of time and money. His investigations must be restricted to what is absolutely required. He cannot carry on elaborate studies, some of which have comparatively little bearing on the particular problem in hand, but tend to build up the science and art of beach protection.

The writer strongly indorses what the author says about the value of inquiries into the history of the particular locality in question, with reference to destructive storms and the fate of structures that have been built at this place. Of the highest importance, also, is the necessity of assembling at the earliest moment such evidence as already exists concerning the probable effects of changes, natural and otherwise, that have been made in the vicinity of the place where the protective works are to be located. As early as possible a rapid survey should be made to see what information may be available and how much reliance may be placed upon it. It will sometimes be surprising to find what useful leads personal testimony may supply. Often this is all the evidence procurable. The opening of the Moriches Inlet and, in fact, the curious behavior of the entire beach at Fire Island, Long Island, N. Y., since the earliest times, have much light thrown upon them when such information is taken into consideration.

Human testimony sometimes affords the only clews which the engineer can obtain concerning storms; and, it should be emphasized that it is storms, and not average weather conditions, in which he should be particularly interested. Unfortunately, lists of storms are not kept by the U. S. Weather Bureau or any other branch of the Government. Nor is the severity or damage done by them often made the subject of an engineering report.

An investigation of the subject of destructive storms along the Atlantic Coast—their frequency, duration, damage done, and the effectiveness of the measures taken to protect property against them, with the practical lessons to be derived therefrom—would be a valuable contribution for the Federal Government to make.

The writer is in favor of inducing the U. S. Coast Guard to make more definite and accurate records of the weather, and he would have observations of high and low tide, the angle of approach of the waves, the height of the tide, and the configuration of the beach included in the log.

More information is needed concerning the general movements of the coast line than can always be had from the maps and surveys that are available. Is the south side of Long Island retreating, for example, and if so, to what extent? Is it subsiding and, if so, at what rate? To what extent does the formation of bays and points along the shore represent continuous tendencies, and how can this be determined when a system of bulkheads and groins, say, 1 000 ft long, is to be constructed?

The author has said little about the movement of sand under the influence of wind and in the regions above the reach of the ocean; and yet this would seem to be an important part of the beach erosion investigations. He has stated that sand traps and their proper use might give considerable helpful information; but, will he not suggest how they should be constructed and used? The quantity of sand moved by the wind toward, and away from, a beach is at times very great. The writer has seen, from a distance, the atmosphere for a height of more than 200 ft look as clouded by sand as from smoke where a fire was raging. More often the sand is swept in drifting currents along the surface of the beach. The writer knows a situation in which the movement of dry sand has considerable effect in determining the proper means of beach protection. The question of sand fixation is closely related to that of beach erosion and is by no means a simple matter.

The writer is in hearty accord with Colonel Brown as to the need of placing as long a stretch of beach as practicable under the protection of a single comprehensive scheme, but he does not see how an engineer who is called on to build a structure in front of a house or along any other limited water front can control this very important matter. No matter how well his work is done, if the scope is not adequate, the result will be more costly and less effective than it should be.

Among the elements of design mentioned by the author one which seems especially worthy of endorsement is the need of keeping the water from getting behind a bulkhead; this is imperative, whether it gets there over the top or around the ends. It is almost impossible to get such water out, once it gets in; but if the author has some simple way of accomplishing it, it is hoped he will describe it in his closing discussion. It seems much better to keep the water from getting behind the bulkhead in the first place. It may be prevented from getting around the ends by bringing them back to high land or to another bulkhead, if there is a good one at hand; but against water coming over the top the best plan seems to be to back up the bulkhead to the top with sand or other solid filling, and keep it filled. The author seems to think this is not a very expensive procedure, but the writer believes it is generally so. Suction dredging is, by no means, always available. It is not practicable on the open seashore unless there is a plentiful source of supply in the rear, and any other method of handling sand is expensive.

JAMES J. O'ROURKE,[6] ESQ. (by letter).—Under the heading "Observations on Design of Protective Works" Colonel Brown suggests a "bulkhead and groin system" or a "groin" system. These will be successful where there is a considerable quantity of sand carried by the littoral drift. Otherwise, such groins are unsuccessful and Colonel Brown recommends that an artificial supply of sand be pumped between the groins, but admits that this supply may have to be renewed from time to time. This requires considerable money for maintenance.

[6] General Eng. Designer, Chicago Park District, Chicago, Ill.

The Outer Drive in Chicago, Ill., through Lincoln Park, extends parallel to Lake Michigan from North Avenue to Fullerton Avenue. The east curb (that is, the one nearest the Lake) is separated from it by a paved concrete beach about 60 ft wide. The elevation of the drive is about + 10. The paved beach slopes from the roadway at Elevation + 10 to the old sea-wall at Elevation + 2. The elevation of Lake Michigan since 1919 has averaged about 1 ft below datum. In 1929 there was an unprecedented rise in the waters of Lake Michigan to an average level of above + 2 during the summer months, which is the approximate elevation of the top of the old sea-wall. This rise, accompanied by strong winds off the Lake, destroyed part of the drive.

FIG. 12.—ELEVATION OF PARTLY SUBMERGED SEA-WALL

In 1930 a series of groins each about 500 ft long and spaced 600 ft apart were built along this stretch of roadway and shore line, inclined at an angle of about 70° from the north, the idea being that a considerable quantity of sand would be accumulated between the groins and thus protect the roadway from future storms. These jetties did not accumulate any sand in the 9-yr period since that time because there is practically no littoral drift at this point. Fortunately, however, there has been no high water since 1929 and no further damage has resulted on account of storms.

FIG. 13.—SECTION OF BEACH SHOWING STILLING ACTION OF UNDERTOW

In 1939 the Commissioners of the Chicago Park District, who control the shore line of Lake Michigan at this point, decided to build a bathing beach with the two-fold purpose of protecting the roadway from future storms and creating much needed bathing facilities for the people of Chicago. In 1938, 1 800 ft of bathing beach had been completed.

A partly submerged bulkhead (Fig. 12) was constructed, joining the lakeward ends of four adjoining jetties. This formed three bays, each 500 ft long and 600 ft wide, into which sand was pumped to an elevation of + 5 at the old sea-wall and + 8 at the new, partly submerged bulkhead. This created a sloping beach from a point about half-way up on the old paved beach to the new bulkhead, the old sea-wall being covered up in the operation and no longer serving any purpose.

This method of shore protection differs from that recommended by Colonel Brown in that the bulkhead is eliminated at the shore end of the groins and the partly submerged bulkhead substituted at the lakeward end. The advantages of the latter over the former are:

(1) It is much cheaper; the partly submerged bulkhead costs from one-third to one-quarter as much as a sea-wall along the shore; and,

(2) It effectively holds the sand behind it, whereas with the former the danger of sand being carried away is always present.

In operation, the partly submerged sea-wall breaks up the sea in this manner. The portion of the wall above the water partly impedes the waves. All the water that passes over it must return to sea in some way. It goes back in the form of an undertow along the bottom. When this undertow reaches the submerged part of the sea-wall it cannot travel any farther along the bottom. In order to reach sea it must rise to the surface of the water and then, in trying to escape, it encounters the sea coming in, thus causing a stilling action at the wall. This is shown in diagram in Figs. 13 and 14.

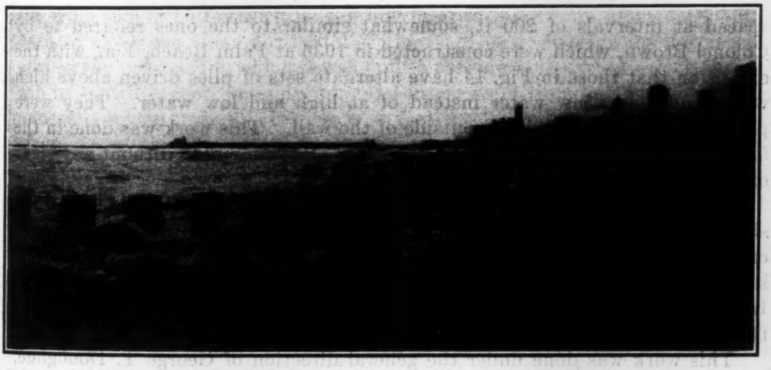

FIG. 14.—SHORE-LINE WAVES AT SEA-WALL; NEW NORTH AVENUE BEACH, LINCOLN PARK, CHICAGO, ILL.

Fig. 14 is a view photographed on March 27, 1939, with a wind of 30 miles per hr blowing from the northeast at about right angles to the shore. It was taken at low water, approximately Elevation − 1. Just to the left of the partially submerged sea-wall are partially submerged jetties 75 ft long and spaced at intervals of 200 ft, somewhat similar to the ones referred to by Colonel Brown, which were constructed in 1936 at Palm Beach, Fla., with the exception that those in Fig. 14 have alternate sets of piles driven above high water and below low water instead of at high and low water. They were placed to reduce scour on the outside of the wall. This work was done in the fall of 1938 and has withstood the storms of one full winter without any signs of movement.

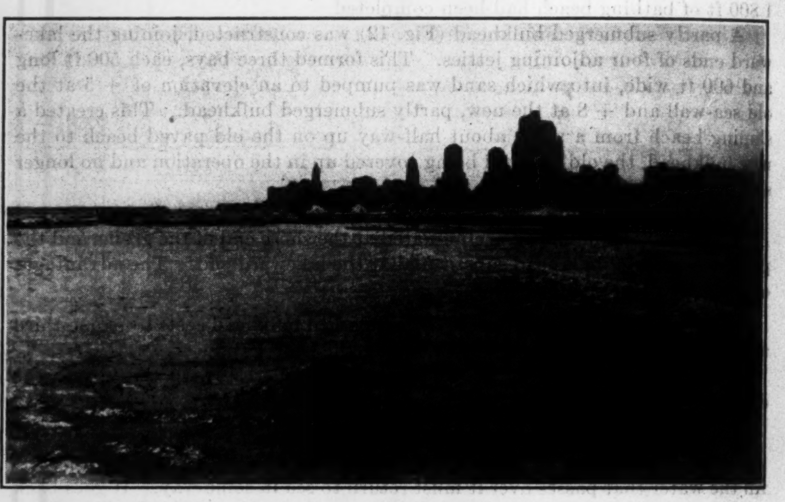

FIG. 15.—SHORE-LINE WAVES BEHIND SEA-WALL; NEW NORTH AVENUE BEACH, LINCOLN PARK, CHICAGO, ILL.

Fig. 15 shows the beach behind the wall, the waves gently lapping on the shore, their force dissipated by it. In contrast the waves from the open sea can be seen pounding against the old sea-wall in the distance. The partly submerged sea-wall has the high buttresses spaced at intervals of 27 ft 11½ in. In future installations this interval will be reduced to 14 ft to assist in breaking the waves at high water.

This work was done under the general direction of George T. Donoghue, M. Am. Soc. C. E.

ELLIOTT J. DENT,[7] M. AM. SOC. C. E. (by letter).—The information that should be secured before undertaking the design of shore-protection works is described fully in this paper. The list of items appears formidable, but the full investigation of one site will ordinarily supply many of the data needed for other sites in the same general vicinity, and the assembly of basic regional data in the files of the Beach Erosion Board often reduces the time, expense, and effort that might otherwise be required when a particular project is under consideration.

---

[7] Col., U. S. Army (*Retired*), Washington, D. C.

The author states that: (*a*) The ratio of length of groin to interval between groins should be between 1 to 1 and 1 to 3; (*b*) spacing closer than 1 to 1 does not injure the beach, but is never economical; and (*c*) spacing greater than 1 to 3 appears to be ineffective. He also states that, subject to the above limits, the correct spacing may be found by drawing through the outer end of a groin a line parallel to the direction of wave approach. The projection of this line upon the beach will give the proper interval.

Along a straight section of beach the axis of wave approach rarely makes an angle of as much as 20° with the perpendicular to the shore. If a line parallel to this axis is drawn through the outer end of a groin, the point of intersection with the beach will be less than half a groin length to leeward of the base of the structure. The use of this rule for the spacing of groins would indicate that, except for economic reasons, the structures should be more than twice as long as the interval between them. This is more than twice as many groins as the author advocates for the closest spacing, and a strict application of the rules would seldom, if ever, permit a spacing of more than 1 to 1.

Fig. 11 shows the profile of a typical groin of the form advocated in 1933 by the Beach Erosion Board for normal use. Experience has since shown that the top of the inner horizontal section may be lowered to at least 1 ft below the normal berm level without affecting the height or width of the finished berm. The sand level shown in Fig. 11 gives conditions before the beach has been built up to the desired form; when the beach has assumed the desired section the groin should be buried from the bulkhead to some point along the sloping part, or along the outer horizontal section. After a set of groins has accomplished the purpose for which it was built a considerable part of each structure will be buried except, possibly, for brief intervals of time following periods of unusually severe erosion. If there is, in fact, a relation between the best length of groin and the best interval between structures, the question arises as to whether the length should be measured from the outer end to the bulkhead, or only to the point where the buried section begins after the beach has assumed the desired form. The latter would seem to be the more logical choice.

It cannot be too strongly emphasized that groins are, in no sense of the word, breakwaters serving to protect the intervening beaches from direct wave attack. However, they may be designed to control the wave-generated currents in contact with the foreshore, and the distance required by diagonal wave attack to create currents of destructive strength is, therefore, an important item in the determination of the proper interval; this distance is vitally affected by exposure, but only slightly so by groin length.

The adequacy of the sand supply is also an important item in the selection of the proper spacing between groins. With a liberal supply of littoral drift the spacing may be much greater than when a scarcity exists.

Each groin inevitably reduces the volume of sand available for the nourishment of the leeward beaches. During the period of accretion along the windward beach the quantity of sand impounded is definitely deducted from the supply of drift. When the impounding capacity of a groin has been exhausted, the quantity of sand passing the site will be unchanged but, unfortunately, part of the sand stream will be detoured around the outer end of the structure in deeper water and at a greater distance from the leeward shore than would be the case on an unobstructed beach. This results in a wastage of sand, and, to minimize this loss, the number of groins should be held to a minimum and the interval between structures should be correspondingly increased. Economy is not the only reason for using the minimum number. The inadequacy of the supply of beach nourishment to the leeward of well-built sets of groins is a phenomenon that has been observed often and has been the subject of much comment.

The proper length of groin for a given location will depend, in part, upon such factors as the width of berm desired, the slope of the foreshore, the tendency for offshore bars to form, and their location. The proper interval between groins will depend largely upon the adequacy of the supply of littoral drift, and the distance required by nature for the formation of destructive wave-generated currents. There appears to be little or no relation between the best length and the best interval.

The art of shore protection has not yet progressed to a state in which past practice can be safely accepted as correct practice, and existing works should be studied judiciously with a view to the development of better practices. In promoting this principle the Beach Erosion Board has made a photographic and written description of a multitude of existing shore protection structures. A careful examination of this record, including a study of the local conditions, the results accomplished, and the spacing, fails to show the necessity for groins as closely spaced as indicated by the rules presented by the author.

In an address before the American Shore and Beach Preservation Association,[8] the writer advocated the creation of improvement districts, each of which would be responsible for the maintenance of an entire natural subdivision of the shore, usually extending from inlet to inlet. It was assumed that, in most cases, an artificial supply of littoral drift or nourishment would be called for and that it would be to the best interests of the districts to conserve that nourishment after having gone to the expense of placing it upon the beach. It was also assumed that there would be an economic balance between the supply of more sand and the cost of other methods of protection. The writer stated that the best spacing of the groins depends upon a number of factors. The district will be called upon to supply the necessary amount of nourishment; in the immediate vicinity of the point of supply no groins will be required to regulate the movement of the littoral drift; as the distance from the point of supply increases irregularities in the beach will develop and groins may be necessary to prevent excessive local erosion. Groins are expensive to build, expensive to maintain, unsightly, and cause a wastage of sand. The best spacing will depend upon a balance in the cost of a more generous supply of nourishment, more frequent points of supply, stronger bulkheads, more groins, and the general utility of the improvement finally adopted.

---

[8] "The Next Step in Shore Protection," by Elliott J. Dent, *Shore and Beach*, Vol. VI, No. 3, July, 1938.

Ralph F. Rhodes,[9] M. Am. Soc. C. E. (by letter).—As stated by the author, the science of beach erosion is new in the United States and comparatively little information dealing directly with the subject is familiar to the average engineer. This paper, therefore, will be a valuable guide to less experienced engineers in the study of the subject, particularly when a problem for determining the cause of beach erosion and making plans for its arrest or prevention at a particular locality is taken up. The author covers his subject comprehensively, and very properly warns the inexperienced engineer against adopting a plan for a particular locality without full consideration of all factors contributing to the destruction of the beach or simply because such a plan has proved effective elsewhere. All plans made for the protection of a beach are, to a certain extent, experimental; but they should be based on the scientific application of all pertinent available data to the problem involved. In the writer's experience, when a beach erosion problem arises and a system of protection works is being planned, usually the plans recommended locally as "certain to do the work best and cheapest" are many and varied in character.

The writer's studies of problems of beach erosion and protection have been confined principally to the coast of Georgia in what the author calls the "South Atlantic Subdivision of the Atlantic Coast." The Georgia coast is part of a long swinging curve extending from the North Carolina capes to the central part of the east coast of Florida. This curve so affects tidal ranges that, while mean ranges are about 3.5 ft and 4.0 ft at the northerly and southerly end of the curve, the value is increased to about 7 ft at Tybee Light, Georgia. The corresponding spring ranges of tide are 4.2 ft at Cape Hatteras, North Carolina, 4.7 ft at Daytona Beach, Fla., and 8.0 ft at Tybee Light. At Cape Hatteras, high water occurs 6 hr and 56 min after the moon's meridian passage, while at Tybee Light it is 15 min later. In general, this tends toward the generation, during a rising tide, of a southerly current along the shore between the two points.

In Georgia, the principal beach erosion problems occur on the ocean shore of the string of islands which form the coast line. These islands are separated from each other by deep sounds scoured out by the swift tidal currents generated by the large tidal ranges on this section of the coast. Some of these sounds are at the mouths of large inland river systems, while the others are the outer ends of large estuaries which project far into the mainland.

The large tidal volumes moving through these sounds necessarily affect the currents along the ocean beaches for a considerable distance on each side of the inlets and, consequently, the sand movement along these beaches. The inlet currents interfere with the general movement of littoral drift toward the south, building it into bars outside of the sounds and pushing the longshore drift out to sea. This robs beaches immediately to the south, of a supply of sand which otherwise they would normally have. These conditions are affected still further by the winds, which vary considerably in direction and intensity. The problems in a beach erosion study in this section are, therefore, vastly more complicated than they are where the beaches are continuous for long distances, the inlets small, and the tidal currents through them moderate.

---

[9] Prin. Engr., U. S. Engr. Dept., Savannah, Ga.

The author calls attention to the necessity for a study of the changes in the offshore depths. Such a study is important in the vicinity of large inlets, especially where these have built bars immediately to the seaward of the mouth. The extent of such bars affects the location and intensity of the tidal currents entering and leaving the inlet, frequently in such a way as to crowd them in close to the shore line. Under these conditions, rapid erosion of the beaches, especially in the immediate vicinity of the inlet, may be expected due to the fact that all beach material broken down by wave action is carried away rapidly by the accelerated currents along the shore.

As pointed out by Colonel Brown, a knowledge of the geology of the beaches is helpful in solving their erosion problems and designing the protection works. The islands of the Georgia coast were once offshore bars and probably very much more extensive than they are now. Before they became covered with vegetation and trees, sand blew over them and covered extensive areas of marsh between them and the mainland. Since this time, the sea has recaptured a large part, if not all, of the areas occupied by the original islands so that, in some localities, the present islands consist only of the sand that was carried landward over the bars during prehistoric times. As the ocean shores of these islands erode, a chocolate colored "rock," consisting of a hard mixture of marsh mud and sand, is exposed on the beaches. Although such material may not materially affect the rate of erosion of the beaches, it does affect the design of protection works, at least as to their foundations.

In the study of the shore-line changes and changes in offshore depths, which is an important part of a beach erosion study, a most valuable source of data is found in the U. S. Coast and Geodetic Survey charts. These charts, however, must be used with caution when comparing those of different dates. They usually contain a note such as "Surveys to 1900." This does not necessarily mean that the whole chart was corrected to show conditions as they existed in 1900. What is meant is that the 1900 chart has been revised in certain portions to incorporate data obtained in 1900. Other portions of the chart may show shore lines and offshore depths based on data of a much earlier date. Without knowledge of this fact and just where on the chart the revisions were made, the student may come to the erroneous conclusion, from comparison of charts of different dates, that shore lines and offshore depths in certain areas have remained stable. In such studies it is necessary, therefore, to obtain from the U. S. Coast and Geodetic Survey copies of the field sheets which show the particular area in which revisions have been made, and use them instead of the whole chart. In 1934 the South Atlantic coast line was mapped by aerial methods, and new general surveys were made of offshore depths. The latest editions of these charts are based on these data and show throughout the chart area conditions as they existed in 1934.

As stated by the author, the cost of securing aerial photographs for a section of beach for a small study is prohibitive. This probably refers to photographs made with regular aerial mapping equipment. It may be found, however, that aerial photographs taken by an amateur with ordinary photographic equipment are valuable in supplementing other data. Small planes are often available at reasonable hourly charges, so that flights over a section of beach at relatively frequent intervals may be made at small expense. Photographs so made show changes produced by periods of good and bad weather, and even if the pictures are taken at an angle with the vertical which is not too large, they may be corrected in an ordinary machine during enlargements. The degree of enlargement may also be adjusted, so that their scales are convenient for use in comparing them with maps made by ground methods.

Beach protection works may be divided into two general classes: (*a*) Sea-walls, and (*b*) groins. In certain cases, the two classes may be combined to form a system with a bulkhead parallel to the shore and connected groins perpendicular thereto, extending below the low-water level. Generally speaking, a sea-wall alone is not expected to recapture lost beach area, but only to hold the shore line against further erosion and to enable property in the rear to be developed. The details of construction depend on whether beach area is being lost and deep water is moving shoreward or whether the low-water line is stationary and the high-water line is moving landward. In the former case the sea-wall must be of heavier construction and its seaward toe well protected from undermining.

The degree of protection ordinarily afforded by a system consisting of a bulkhead and groins is measured, to a large extent, by the amount of sand entrapped and held between the groins and in front of the bulkhead. The groins in themselves offer little protection to the shore line. Their office is to collect and hold sand against the bulkhead, leaving the remainder of the protection to be furnished by the bulkhead structure. Although this structure must be made strong enough to withstand the force of the seas while the sand is collecting in front, it ultimately gives protection only against waves which reach higher elevations than the accumulated sand between the groins.

In designing a system of protective works for a beach which is eroding, full consideration should be given to the length of shore line which should be covered by the protective works. If this is not done, it may be found, after the works are erected, that adjacent sections are beginning to erode which have never before showed signs of cutting back. It may also be found that, as the works are being constructed, the process of erosion is accelerated in adjacent locations where works have not been started. This is because the protective works have trapped sand which was the usual supply of beach building material for the other sections of the beach and the damage has simply been transferred from one locality to another. The susceptibility to such occurrences is greatest in localities where the supply of moving sand for maintaining the beaches is limited. Therefore, the construction program for such conditions should be based on full consideration of probable changes in weather in that part of the beach where no works are yet erected as construction proceeds in the other part. Similarly, consideration should be given to the effect of groins partly or wholly completed on other parts of the beach during sudden storms or other radical changes in the weather.

The author has gone very thoroughly into the details of design of the works for beach protection, and his criteria should not be ignored unless conditions at the locality under study show good and proven reasons therefor. As stated in his first paragraph on the design of protective works, he has assumed shore conditions along straight stretches of beach distant from the influence of an inlet or change in the direction of the shore. For protection against ordinary storm tides and with the land in the rear comparatively low, he specifies that the top of the bulkhead should be placed at an elevation equal to the average height of the highest yearly storm tides plus wave heights. In the vicinity of the mouth of the Savannah River, this would be about 9.5 ft above mean low water, the height of the storm tide, plus 3.5 ft for the wave heights. These two added together give a total of 13 ft, and if the bulkhead consisted of piles with lengths three times this total, 40-ft piles should be used.

In view of Colonel Brown's requirement that the bulkhead should be tied back, so as to insure against failure from pressure from the fill on the back side of the bulkhead, and braced against impact of the breaking waves on the front side, a penetration of 26 ft below low water may be excessive. A bulkhead so designed does not depend for stability on the structural strength of the sheet-piles at the ground line, the length of these piles below ground being for the most part protection against the wall being undermined. If the worst condition as to scour in front of the bulkhead is assumed, below which no erosion can take place, then the length of piles below this level need be only sufficient to prevent blowing out beneath them from hydrostatic pressure at the rear. A similar analysis for length of pile beneath the level of most severe erosion should be made for groin structures as well. Where brace piles are used, these members are designed for, and intended to take up, all stress due to shock of wave action, and the sheet-piling below the level of most severe erosion is only for the purpose of preventing a blowout beneath the groin due to hydrostatic pressure. In a groin where no brace piles are used, sheeting must take up wave shock also; and in determining its penetration, its length in undisturbed material and the nature of the material must be considered.

On a curving shore approaching a large inlet, the rule laid down by the author for the location and spacing of groins on a straight beach cannot be applied near the inlet. No exact rule which can be used as a guide is known to the writer, but data should be available as to directions and velocities of the currents in and near the inlet at various stages of the tide and at several distances from the shore. How these currents are affected by winds from several directions should also be known. From consideration of these data, it will probably be found that the groin spacing should be less near the inlet than that found correct for a straight section of the beach at a greater distance from the inlet. It will also be found that the pointing of the groins should be about normal to the shore line, the last groin being about at right angles to the axis of the inlet and as far inside as erosion from waves may occur. After reaching this point, it may be found necessary to extend the groin system along the shore into the gorge as far as erosion from inlet currents is taking place. The design for such a groin system, therefore, gradually changes from one based on the specifications laid down by the author for a straight beach to one based on specifications for bank protection against lateral currents.

As Colonel Brown states, there is still need for additional research and study. Well-directed inquiry, however, will disclose considerable useful information of which little is known to the engineer who is engaged in general practice only and to whom the science of beach protection is a comparatively new subject. Such information or references to it can be had for the asking by applying to the Beach Erosion Board mentioned in this paper. However, the engineer who expects to have beach erosion problems presented to him for solution should be continually on the lookout for other information on the subject, especially as to the history of structures already built in other localities where beach, weather, and current conditions are similar to his own.

CHARLES T. LEEDS,[10] M. AM. SOC. C. E. (by letter).—The author has given an excellent syllabus of beach erosion study with an enlightening commentary thereon. Beach protection is a most fascinating and a most tantalizing field of engineering, because of its many elusive and often indeterminable factors. In a field of science which is so largely empirical the wise engineer will search all possible sources of information. Therefore, such a general outline as the author gives of a typical study, together with an explanation of the need of each item, is a valuable contribution. Because this field of engineering is so largely based on experience, however, one of the greatest needs is a more extended and detailed record of results under varying conditions, but perhaps such record should be made the subject of another paper.

The engineer who attempts to diagnose the symptoms of an inadequate or menaced beach, and to prescribe remedial measures, is in much the same position as a doctor prescribing for a human patient; for a beach, like a human being, is ever-changing—continually wasting and rebuilding. The first requisite is the past physical record (geologic as well as historic) and all available past surveys and photos should be obtained and supplemented by personal observations, past and present. Even then the records are often too meager and intermittent to afford other than a very broken story of the changes that have taken place in the shore line and in the offshore conditions.

Just here a word of caution is important. Not only the year of the survey, but also the season, should be learned, if possible, for the direction of littoral drift may vary with the time of year. Unfortunately there probably will be no record of the weather at the time of these old surveys; yet this is important, for the beach may recede a considerable distance in a single storm, and in a succeeding period of fair weather it may undergo a more or less complete restoration by natural accretion. Therefore, a given survey or photograph may or may not be representative of the average shore conditions. This is especially worthy of remembrance in case of a dispute regarding title to lands bordering the ocean, for in some instances the land values in question may reach huge proportions.

Where there has been a considerable lapse of time between surveys it is highly important to use these with great care. It is by no means certain that the movement of the shore line between the locations shown on different dates has been either continuous or all in the same direction.

---

[10] Maj., Corps of Engrs., U. S. Army (*Retired*); Cons. Engr. (Leeds, Hill, Barnard & Jewett), Los Angeles, Calif.; State Consulting Seacoast Engr.

The writer recalls an engineer friend who compared two surveys dated, say, 1860 and 1890, and because the river mouth in 1890 was 1 000 ft westward of its location in 1860, he assumed a progressive westward littoral migration of 30 to 35 ft per yr, notwithstanding that the present prevailing littoral drift is in the opposite direction. He assumed, from recorded statements of "old-timers," that southeasterly storms were more frequent and more severe in the Nineteenth Century than they have been in the Twentieth Century, and therefore, that the predominant littoral drift has been reversed. Such a theory of meteorological cycles is not believed to be tenable. It is more probable that the river mouth actually migrated eastward under the influence of prevailing waves from the southwest, until a heavy flood broke out a new mouth well toward the west, when it again resumed its eastward travel. Such a migratory cycle is well known to those familiar with inlets on sandy coasts where there is a predominant littoral drift. The survey of 1860 probably showed the river mouth at nearly the eastward limit of its migration during a dry period, whereas the survey of 1890 probably showed its position just after a heavy flood, at the beginning of its migratory cycle.

In discussing the need for study of past wind and weather conditions, the author might well have given even greater emphasis to the statement that "If it is apparent that there is a great seasonal variation in wind direction and intensity, and if the detail of the study warrants, such wind-roses should be plotted for each month." The writer has seen (as have doubtless many others) a single storm, in a short time, undo the work of the prevailing wind movement over a long period. Such information will not receive adequate attention in a wind-rose showing the aggregate of all observations over an extended period.

A very important item of information, of which there is seldom adequate accurate record, is that of wave data. It is true that the author states (see heading "Field Work: Wave Data"): "Whenever observations on currents in the ocean or sand in suspension are made, careful readings of wave data should be made and recorded." However, such records can be only fragmentary and are pertinent only for the times of the "observations on currents in the ocean or sand in suspension." Wave action undoubtedly constitutes the major factor in littoral sand movement; therefore, the wave direction, velocity, height, and especially duration are even more important than the wind direction and velocity. Indeed, serious beach erosion is sometimes caused by severe wave action occurring in periods when there is no appreciable local wind, these waves being the result of distant storms.

As the author states (see heading "Scope of a Beach Erosion Study: Littoral Drift"): "* * * the direction of predominant littoral drift * * * is most important in the design of a protective system," and "If the detail of the study permits, observations as to the direction of littoral drift should be continued over a period of a year to determine these seasonal changes." Yet current measurements and sand samplings are admitted to be impracticable, except under relatively calm conditions, and to continue them over an extended period, such as a year, is often unduly expensive.

What is needed is the summation of all movement of the sand, landward or seaward, and upcoast or downcoast. By placing, on the beach, some material of approximately the same specific gravity as the beach sand or gravel, but easily distinguishable therefrom, and by observing the location of this material periodically, the aggregate movement can be recorded. The writer feels that inadequate efforts have been made in this direction, although he recognizes the difficulties. For instance, in one case, an engineer had small piles of brickbats placed on the beach at about mid-tide, only to find later that children and picnic parties had used them to build picnic fireplaces and toy castles on the beach beyond reach of the waves. Notwithstanding this discouraging experience, it is still believed that some modified application of this procedure is practicable. Pea coal or any obtainable sand and gravel clearly distinguishable from the local beach material would be satisfactory.

One pertinent factor not mentioned by the author, which has much to do with beach maintenance in regions where detritus from the upland constitutes the major source of beach material, is the magnitude and frequency of flood flows. It has been noticeable in California that during years of little rainfall complaints of beach erosion become very prevalent, whereas in years following heavy rainfall and floods shore communities are wont to boast of their wonderful beaches.

Flood control measures which include long jetties at the river mouths, designed to stabilize and maintain these outlets by delivering the flood-borne sand into deep water, are likely thereby to result in beach starvation by depositing the major part of the sand beyond the reach of ordinary wave action instead of near the shore line as in a state of nature. Similarly, upland debris control measures, although most meritorious in preventing land erosion, must inevitably deprive the beaches of much of their natural replenishment. As a consequence, engineers must look forward to an increasing demand for beach protection.

In all these preliminary investigations, it is believed that the chief danger lies in attempting, or being forced, to draw conclusions from data which are necessarily, or otherwise, inadequate. This inadequacy may be the fault of the engineer through his lack of experience; or it may be beyond his control, due to lack of available funds or non-existent historical records.

The effort of an individual to protect his property from marine inroads is not unlike that of a property owner on a river to protect himself from flood damage. Not only is it far more expensive if done individually than if done in cooperation, but it is far less effective and sometimes almost hopeless. Just as flood control, to be effective, must be designed with the entire drainage basin in mind, so shore protection, to be most effective and economical, must be designed with due thought for the influence from and upon a very considerable extent of shore line. Wherever feasible the coast line should be divided into such sections or stretches as can be considered independently of each other. Then for each section a protection system, such as a "groin field," should be planned before undertaking the construction of any individual part.

The only adequate solution of a beach improvement problem lies in such "coastal planning" considering a stretch of beach of sufficient magnitude to be treated as an independent and complete unit. By thus envisaging a future comprehensive system, the engineer can lay out the most suitable ultimate location for high-water mark and determine the length, number, and spacing of groins which will best produce this result. Parts of this system can then be constructed from time to time with the assurance of an ultimate co-ordinated whole. However, if each property owner is concerned only with the protection or improvement of his own property, he will devise a plan to fit his own selfish ends, which may (but probably will not) harmonize with a general plan which would be best for the public good. The writer realizes fully that this ideal policy is usually practicable only for the publicly employed engineer, and that the engineer employed by an individual owner can seldom consider aught but the interests of his own client.

Furthermore, in most States, the individual riparian owner is legally limited by the "common enemy" doctrine of law. He may erect structures of only such nature and extent as will protect his own property from inroads of the sea. If he limits himself carefully by this requirement, any consequent damage to his neighbor's property is "damnum absque injuria," or injury without legal wrong. However, if he goes beyond work purely for protection and endeavors to improve his property by widening his beach, then he renders himself legally liable for any injury which may result to his neighbor's property.

When all the property owners join in an improvement or protection district, however, they are then mutually responsible for the work of the district, and moreover, the engineer then has a better chance to so design his work and plan his construction (normally constructing the leeward groin first) as not to cause injury to neighboring property.

Not only is co-operation between beach owners essential to secure the best design of a shore protection project, but it is even more so on the grounds of equity and economics. Very often the cost to an upland owner of providing protection for his property alone is out of proportion to the value of the land, whereas his proportional share of a complete shore protection system would be much more reasonable. Even in the latter case, however, it is often inequitable to expect the upland owners to pay the entire cost of this shore protection. The indirect value to the community of an attractive beach frontage, as well as the direct return to the community in increased taxable value, makes it justifiable for the public to bear some proportion of the total cost.

Much has been written of the unsightliness of groins and the saw-toothed beach line which they produce. It is the high, solid groin which is chiefly responsible for this unwarranted criticism. The remedy lies in low groins, built up gradually as the beach builds up, the portion of the groin shoreward of ultimate high water line being kept at or below the natural beach level. Examples of this may be seen in Fig. 16, which shows low groins, the inshore ends of which have become buried by natural accretion, and which have produced a smooth shore line.

It is also well known among engineers experienced in shore protection that the ideal method of developing a smooth beach is to keep the groins only a few feet above the beach level, and if possible to raise, gradually, the part of the groins seaward of high-water mark as the beach builds up. This ideal is not always feasible, but the writer has used a very effective modification of this system where the groin is of steel sheet piling. Every fourth pile is driven a few feet lower than the remainder, thus leaving "windows" in the groin. At first these "windows" permit the upper part of the wave (which, of course, is carrying the least sand) to pass on through the groin, thereby decreasing the volume of return flow down the beach slope parallel to the groin and increasing the tendency to sand deposit. Later, when the beach has built up to the bottom of the "windows," the sand passes on through them to the leeward side, thereby fostering a more smooth and uniform beach outline. Should it be desired to build the beach level still higher, these "windows" can be closed by short pieces of sheet pile. The beach then builds up to the top of the groin and buries it to a point seaward of the break in the profile. Fig. 17 shows such a groin under construction, several of which have been built by the State of California, and which have functioned very satisfactorily. The shoreward end of this groin was constructed of wood sheet piling for economy, as it later became buried by natural accretions.

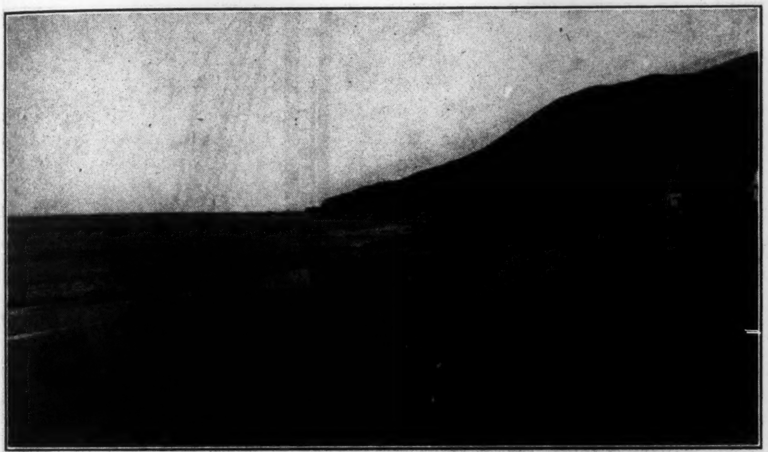

FIG. 16.—GROINS AT LAS TUNAS BEACH, CALIF., SHOWING INSHORE ENDS BURIED BY NATURAL ACCRETION AND RESULTANT SMOOTH SHORE LINE

It is understood that on the Atlantic Coast certain groins have been constructed with these "windows" extending out to the seaward end of the groin and having the bottoms of the "windows" approximately at beach level. It is believed preferable to keep the seaward end of the groin solid, in order that it may tend to divert the littoral drift shoreward where it will be either deposited on the windward side of the groin or pass through the "windows" and be deposited on the leeward side. Every effort must be directed to minimize the amount of sand being diverted seaward around the outer end of the groin where much of it may be lost.

The author touches only lightly on materials of construction, implying that groins will be built of sheet piling. This type of construction is usually the simplest, and steel is ordinarily preferable to wood, unless the cost differential is too great. Steel is particularly suitable where the beach is underlain by material that is difficult to penetrate. Indeed, steel master piles are often preferable to the round wooden piles indicated in Fig. 11.

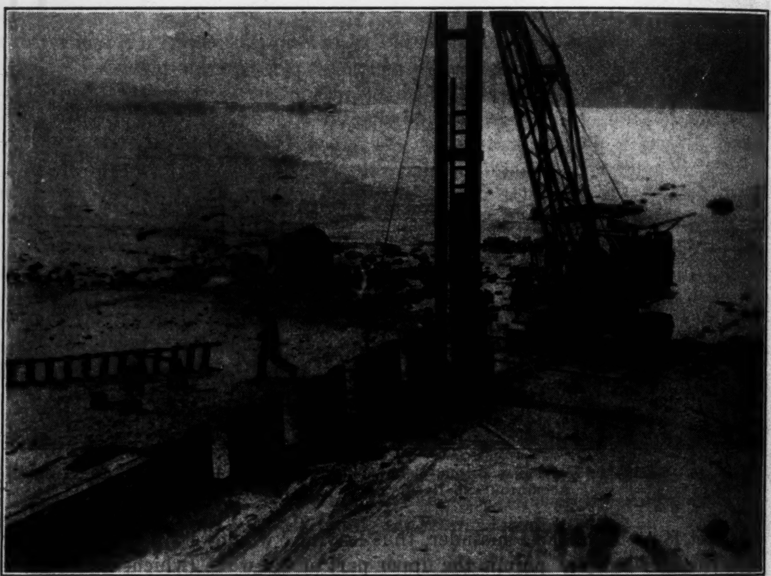

FIG. 17.—STEEL SHEET PILE GROIN, WITH "WINDOWS," UNDER CONSTRUCTION NEAR SANTA MONICA, CALIF.

A strong argument against wood piling is its buoyancy. The writer has seen wood groins fail by becoming loosened in a storm and then "popping" out, without being broken off. Perhaps the penetration was inadequate in these cases, but steel piling would have required less penetration for safety. Sand erosion of the steel is more of a problem than corrosion. Asphalt and sand coating has been found more effective protection than most of the commercial paint coverings.

Sometimes it becomes necessary to construct groins where no type of piling is practicable. Of course, the rock mound type familiar on the New Jersey coast can be used where the groin (or "jetty," as it is called in that locality) is large enough to justify use of rock sizes capable of withstanding wave action; but such structures are likely to be lacking in sand-tightness. Solid concrete

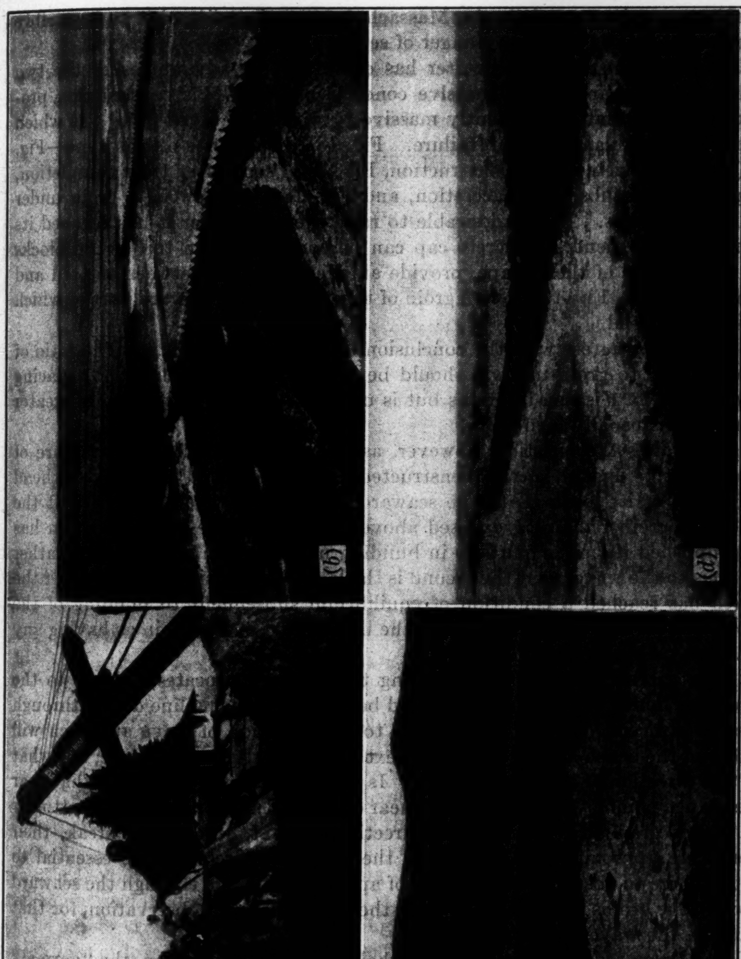

FIG. 18.—CONCRETE BLOCK GROINS, SANTA BARBARA COUNTY, CALIFORNIA

has been used successfully in Massachusetts and California, and possibly elsewhere, where there is no danger of settlement.

In certain instances the writer has combined the advantages of the two types by using articulated massive concrete blocks. This construction produces a groin that is sufficiently massive to withstand storms and yet which can settle irregularly without failure. Fig. 18 shows groins of this type—Fig. 18(*a*) being a view during construction, Fig. 18(*b*) soon after their completion, Fig. 18(*c*) the subsequent accretion, and Fig. 18(*d*) a view of a groin under storm conditions. If it is desirable to raise the groin after it has reached its ultimate settlement, a concrete cap can be constructed on top of the blocks which, because of their shape, provide an effective bond between the old and the new work. Fig. 19 shows a groin of this type, the shoreward part of which has been capped.

The writer agrees with the conclusions of the author that: (*a*) The ratio of groin length to groin interval should be between 1 : 1 and 1 : 3; (*b*) spacing closer than 1 : 1 is non-injurious but is uneconomical; and (*c*) spacing greater than 1 : 3 is usually ineffective.

This raises the question, however, as to what is the effective measure of groin length. Is it the actual constructed length, measured from the bulkhead regardless of its location, to the seaward extremity of the groin, or is it the length of groin remaining exposed above the beach slope after the groin has accomplished its major purpose in building up the beach? It appears rather obvious to the writer that the second is the logical conclusion because, after the beach has reached a condition of equilibrium subsequent to building of the groin, one certainly cannot consider the buried part of the groin as having any influence on wave action.

As a further rule for groin spacing the author advocates, subject to the foregoing limits, that the groins should be so spaced that a line drawn through the seaward end of one groin parallel to the direction of wave approach will intersect the beach at the root of the next groin. This sounds simple, but what is "the direction of wave approach"? Is it that in deep water or is it that near the plunge point? On approaching near enough to shore to "feel the bottom," all waves gradually change their direction so that, when they break, their fronts are approximately parallel to the shore. Therefore, it is essential to know where to observe the direction of approach. A line through the seaward ends of the groins would appear to be the logical point of observation, for that is where the waves are intercepted.

Furthermore, which kind of wave shall be used as a criterion, the "normal" waves, the direction of which is most predominant through the year, or the storm waves, which, although less frequent, are much more powerful? In Southern California the fair weather waves approach generally from the southwest or west and predominate through two-thirds to three-fourths of the year, whereas the southeasterly or southerly storm waves occur only in the three or four winter months. There is little question here in adopting the prevailing fair weather direction. In other localities, however, the problem may be less simple, for the wind and wave direction may be much more variable.

The author's rule for groin spacing, based on direction of wave approach, does not seem entirely clear. He states that "In the case of storm action parallel to the coast the resulting waves do not travel parallel, but the shore ends are retarded so that the wave reaches the shore at an angle of about 16 degrees." Applying the author's own rule to this case would appear to justify a groin interval equal to only approximately one-fourth the groin length, if the angle is measured from the perpendicular, or four times the groin length, if the angle is measured from the shore. It is hoped that the author will amplify his rule.

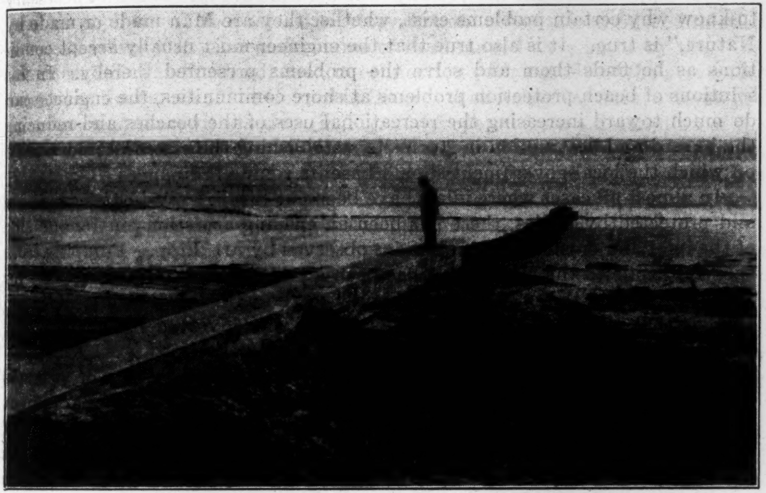

FIG. 19.—CONCRETE BLOCK GROIN, SANTA BARBARA, CALIF. INSHORE END RAISED BY MONOLITHIC CAP

In California the State Division of Lands is gradually accumulating a record of seacoast structures within the State, their behavior, and their effect on the coast line. Since 1931 State permits have been required for construction and maintenance of all structures extending seaward across the State-owned tide and submerged lands. Each applicant is required to submit for approval plans of the proposed structure, a map showing the present (and past, so far as available) lines of low tide, high tide, and extreme reach of the sea in the vicinity, accompanied by photographs. From time to time after completion of a structure, inspections are made and photographs obtained to record the effect produced by the structure on the shore line. By this procedure it is planned to accumulate a reservoir of information that should be of service, not only to the State, but to the engineering profession in future shore protection and development.

EARL I. BROWN,[11] M. AM. SOC. C. E. (by letter).—In general, the publication of this paper has resulted in beneficial discussion.

---

[11] Col., Corps of Engrs., U. S. Army (*Retired*), Wilmington, N. C.

Mr. Lipp discusses the paper from the standpoint of his Florida experience, and gives the reasons for his practices on that shore. He stresses the difficulties encountered at inlets, those arising from heavy surf action, and the other local conditions to which his discussion calls attention. He finds, in general, that his experience corroborates and confirms the views expressed in the paper.

Mr. Lipp's statement that, in any beach erosion study, "It is first necessary to know why certain problems exist, whether they are Man made or made by Nature," is true. It is also true that the engineer must usually accept conditions as he finds them and solve the problems presented thereby. In his solutions of beach protection problems at shore communities, the engineer can do much toward increasing the recreational uses of the beaches and reducing the hazard and destruction in storms by establishing the essential information on which the local government should base its zoning ordinances.

In almost all cases where inlets have been cut through sand barrier beaches and protected by jetties, there has been an ensuing accretion on the one side of the inlet and erosion on the other, as observed by Mr. Lipp. Pumping from the "full" side to the eroded side has been advocated by some individuals for many years, but the only location known to the writer at which it has been tried is that cited by Mr. Lipp. The possibilities involved merit additional study and experimentation.

The starving of beaches to the leeward of a well-built system of groins is familiar to all students of the subject of beach erosion and is another argument in favor of comprehensive planning for the development and protection of entire beach areas. To take care of the original filling of groin bays, it is advisable, of course, to start the construction of a system of groins with the most leeward. Unless there is known to be a large littoral drift, the necessity of maintaining the beach by artificial filling between groins must always be considered when developing a plan of protection.

Mr. Soper expresses opinions probably held by many practicing engineers concerning the elaborateness of the investigations recommended in connection with beach erosion studies. It is probably true that many problems in connection with shore protection have been solved successfully "at the least expenditure of time and money." On the other hand, the practice of designing and constructing beach protective works on little or no real information is dangerous and has been the cause of the wasting of millions of dollars. It is the writer's opinion that much of this loss might have been saved if the investigations had been more complete. The recommended investigations prior to construction (particularly as to geology, shore-line and offshore changes, wave action and storm effect, tidal and other current conditions, character and extent of littoral drift) are as necessary as foundation investigations for buildings. If direct data are not obtained, practicing engineers are forced to base decisions on criteria taken from existing construction which has proved successful. The weaknesses of this condition are well known to the engineering world. It is to be understood that the scope of the investigations to be made in each particular study will be based on local conditions, available information, and the problem involved. Each of the different investigations should be made only when it is known that the results will have an important bearing on the problem.

Mr. Soper, very properly, emphasizes the desirability of inquiries into the history of destructive storms and their effects on structures. He also suggests the value of personal history as to local conditions. In these views the writer concurs fully. He states that the paper does not discuss, adequately, the movement of sand under the influence of the wind. This omission is acknowledged, and is to be attributed to the fact that few observations are available on this subject. The most satisfactory known observations on the relation between velocity of wind and volume of sand moved were made by the U. S. Engineer Office at Portland, Ore., in connection with a study of the movement of sand at the mouth of the Columbia River. A sketch of sand traps developed in connection therewith is given in Fig. 20 (prepared from a description of the trap used by Morrough P. O'Brien, M. Am. Soc. C. E., and B. D. Rindlaub, Lieutenant, Corps of Engineers, in tests at Clatsop Beach, Ore.[12]). When it is recalled that the sand dunes along the coast are formed from wind-blown sand, its importance in the study of coastal phenomena may be appreciated. Although the removal of sand from the beach by wind undoubtedly affects the rate of erosion, statistical data are meager. Mr. Soper also queries whether any method of removing the water behind a bulkhead can be suggested. The writer believes that every effort should be made to prevent water from seeping behind a sea-wall or bulkhead, but, when once there, no satisfactory way to remove it is known except to provide a suitable opening for drainage in the wall, so constructed as to prevent the escape of back-fill material. The writer deems that a bulkhead that is not completely back-filled is not a complete structure, and that if the economics of the problem do not justify the cost of a back-fill, some other solution of the problem should be sought.

[12] An unpublished report to the District Engineer, Portland, Ore.

Mr. O'Rourke has made a considerable contribution to the art of shore protection in designing his submerged bulkhead. This structure appears to be well suited for conditions on the Great Lakes where it was constructed. There may be some question as to its effectiveness on an ocean beach where tidal variations may reduce its beneficial effects at the higher stages of the tide. An attempt to accomplish a similar result on the ocean beach has been devised experimentally by Mr. Richard Arpen, in the form of a triangular concrete block termed a "submerged breakwater." It appears to have had some beneficial effect in trials.

Mr. O'Rourke's description of the partly submerged bulkhead is of great interest. In several instances known to the writer, the construction of offshore breakwaters has been followed by a building out of the beach behind it. As a general rule, the high cost of offshore structures precludes their use solely for the purpose of beach protection. An experimental study of such structures has been made by the Beach Erosion Board in its experimental laboratory at Washington. The preliminary results appear to justify further study, both in the laboratory and the field.

Colonel Dent and Major Leeds question the rules used by the Beach Erosion Board in determining the ratio of length of groin to interval between groins. These rules are entirely empirical and cannot withstand logical analysis. However, observation of installed groin systems indicates that the rules may be relied upon, generally, to give a reasonable layout for a groin system. These writers also raise the point as to whether the stated length of groin is the total length or the length protruding after a sand fill has accumulated. It is customary to consider the length of structure as built; a groin system functioning with 100% efficiency would be practically buried by the accumulated sand.

Colonel Dent states that the best spacing may depend on a balance of the cost of a more generous supply of nourishment (presumably by artificial means), more frequent points of supply, stronger bulkheads, more groins, and the general utility of the improvement finally adopted—that is, on the economics of the problem. There are many cases where economical considerations require the adoption of a project for erosion control less expensive than the ideal solution. Such a case has arisen in the writer's experience in designing a beach-erosion control project for the Town of Wrightsville Beach, N. C.

The frontage to be controlled was about 12 000 ft long, and the cost had to be kept within the sum of $250 000. The ocean was rapidly encroaching on, and endangering, existing structures, and it was desired to provide a safe margin of protection as rapidly as possible. The design made by the Beach Erosion Board for the locality comprised a groin and bulkhead system estimated to cost about $750 000, but such a sum was entirely beyond the capacity of the locality to finance. Its legal bonding limit confined its efforts to the aforementioned sum. The design adopted to meet these limitations consisted of an extension of the berm seaward for distances of from 100 to 200 ft by sand artificially supplied by dredging from the lagoon in the rear of the island on which the town is located, and the fixation of the artificially created beach by a system of sixteen groins. The latter are of creosoted timber constructed in general accordance with the Beach Erosion Board's typical design, with some modification, particularly at the outer end, to prevent erosion by eddies around the ends. The inner part of the groins is not horizontal but slopes from Elevation 9.5 ft (M.L.W.) at the landward end to Elevation 8.5 ft at a point 90 ft seaward; thence it slopes for 140 ft down to Elevation 2.0 ft; and then extends seaward horizontally for 95 ft, making the total length of groin 325 ft. It was possible to provide only sixteen groins to cover the distance of 12 000 ft; hence the spacing was about 800 ft. The volume of sand supplied to extend the berm seaward as desired, and to fill the intervals between groins substantially to the tops of their inner and middle sections, was 700 000 cu yd. The groins were practically buried within the fill since their function was to stabilize the berm and not to create one by accumulating drift. This project is functioning satisfactorily.

Mr. Rhodes discusses the paper in the light of his experience on the Georgia coast where he finds beach problems very intimately involved with those of currents at inlets, and their subsidiary effects. He finds that, in general, the experience and practices described in the paper correspond with his experience. He points out that at, and in, inlets the rules for spacing groins should be modified to require quite close spacing, as the problem there becomes one of bank protection rather than one of shore protection.

Major Leeds also finds it necessary to make an extended research into the past history of a beach under study in formulating a design for protective works, and he stresses the necessity for the use of good judgment in interpreting the available data. He stresses in particular the desirability of the fullest and most complete data possible as to winds and waves. He considers wave data more important than wind data.

Major Leeds advocates the study of the residual movement of some material placed on the beach, of approximately the same specific gravity as the beach sand or gravel, but readily distinguishable therefrom, and a periodic observation of its aggregate movement. The Beach Erosion Board has attempted to make such studies,[13] using a red sand in lots of 16 to 20 cu yd each, placed in a trench extending from the crest of the berm to mean sea level. It found that this material became so diluted by mixture with other materials that its travel could not be followed along the beach for any considerable distance, and that in a short time it could not be identified at all. Further experiments with larger volumes of foreign materials might yield further information.

Major Leeds calls attention to a matter of grave concern to beaches on deeply indented and rocky shores, such as those of California. Many of these beaches are fed by detritus brought down to the sea by mountain torrents. The improvement of the valleys of these torrents in the way of flood-control and erosion-control projects is likely to reduce or eliminate such supplies, resulting in great damage to the beaches.

Major Leeds makes many valuable suggestions on groin design, some of which do not agree in detail with the recommended design. These comments are appreciated, although it was conceded in the paper that many variations in design of groins are permissible under certain conditions.

---

[13] Interim Report, Beach Erosion Board, April 15, 1933, paragraphs 3/1 to 3/6, inclusive.

Regardless of the methods adopted, the cost of beach protection is high. Engineers studying beach problems should take full cognizance of the necessary relationship between the cost of protection and the value of the property to be protected. The general public readily endorses the construction of a shore boulevard or boardwalk at costs of \$25, \$50, \$100, or possibly more per running foot. The necessity of proper expenditures for the protection of the beach itself should be apparent but it is often disregarded. There are more than sufficient examples to warrant the advocated principle of the Beach Erosion Board that upon decision to build, it should be axiomatic to build carefully and strongly. This does not prevent the possibility of savings in construction costs based on intimate and detailed knowledge of local conditions probably beyond the scope of a study by the Board.

As stated in the original paper, the science or art of shore protection is comparatively new. Sound judgment based on careful observation and critical analysis of existing beaches and structures is, and will remain for many years to come, the principal tool of the beach protection engineer. Quantitative methods of predicting any aspect of shore-line behavior are almost nonexistent and the subject is of such nature that it will not soon be presented in handbook form.

Shore-line behavior, however, is uniquely related to the hydraulic phenomena at work and the difficulty lies not in mysterious phenomena or insuperable difficulties in observation and interpretation but rather in the extreme variability and uncertainty regarding the sequence and magnitude of the winds, tides, currents, and sand supply. Hydraulic models of typical or specific situations, if built to sufficiently large scale, would undoubtedly yield reliable data concerning major phenomena but one is always uncertain about the manner in which the controlled variables are to be introduced.

The large number of variables involved in every study of the forces acting upon the shore line emphasizes the necessity for comprehensive planning after thorough consideration of all detailed information that can be secured, in order that there will be no possibility of overlooking any clue to the best possible solution.

In conclusion the writer wishes to express his appreciation to those who have discussed the paper, and his indebtedness to the Beach Erosion Board for valuable assistance.

SETTLEMENT STUDIES OF STRUCTURES IN EGYPT

By Gregory P. Tschebotareff,[1] M. Am. Soc. C. E.

With Discussion by Messrs. L. C. Wilcoxen, Trent R. Dames, Edwin J. Beugler, W. S. Hanna, D. P. Krynine, and Gregory P. Tschebotareff.

Synopsis

Systematic settlement observations are described, in this paper, of a number of new buildings—public and private—constructed within a radius of several hundred miles. Foundations of every conceivable type were included, and the observations were combined with comparative investigations in the laboratory—all based on the principles of modern soil mechanics.

The organization of these studies is outlined herein, as conducted by the Foundation Soils Research Laboratory of the Egyptian University, at Cairo, Egypt, with the support of the Egyptian Government and the co-operation of local consulting engineers, architects, and contractors. Emphasis is placed on the methods of overcoming the prejudice, ordinarily encountered by practising engineers and architects of all countries, against settlement observations of their structures by independent third parties.

Some of the most important results of studies on eleven of the new structures are presented in graphical form. A comparison is made between modern theories and the results of laboratory tests. The effects of these studies on new trends of local engineering practice are outlined. Conclusions are presented concerning the features considered as being essential for the successful organizations of such studies in any other locality.

Beginning of Settlement Studies in Egypt

Evidence of settlement is to be found on numerous structures erected on the clays and silts of the Nile Valley and Delta. Unforeseen and particularly great difficulties were encountered by the settlements of a large public building erected in Cairo about 1928. Its completion had to be delayed for more than

---

Note.—Published in October, 1938, *Proceedings*.

[1] Asst. Prof. of Civ. Eng., School of Eng., Princeton Univ., Princeton, N. J.; formerly, Research Engr., Foundation Soils Research Laboratory, Egyptian Univ., Cairo, Egypt.

three years until continued observations showed that the rate of settlement had decreased to a reassuring extent. Tests on clay samples and a settlement analysis made by Professor Dr. F. Kögler at his laboratory, in Freiberg, Germany, also showed that the period of consolidation was nearly ended. Some of the settlement observations and other data pertaining to this building (identified herein as Building *T*) are shown subsequently on Figs. 13 and 14. The case attracted attention to the numerous "gaps" in the engineering knowledge concerning the behavior of foundations and to the methods recommended by the new science of Soil Mechanics for the purpose of closing these gaps.

An extensive study of settlement problems was decided upon and the writer was engaged to organize a Foundation Soils Research Laboratory.

Purpose of the Settlement Studies

An investigation was planned of all problems connected with settlements. In particular, the studies undertaken were:

(*a*) To provide the local Engineering Profession with accurate knowledge concerning the final value, the rate and the distribution, in plan, of settlements as observed on actual structures erected on different types of foundations and on different local soil deposits (the factors influencing cracks and other damages to the superstructure were to be established); and,

(*b*) To allow comparisons between the settlement values as actually observed in the field and as forecast on the basis of computations and of laboratory tests; the theoretical methods of analysis were to be corrected and developed by means of such comparisons.

Organization of the Settlement Studies

The following principles guided the organization of the settlement studies:

(1) The studies were classified as a research in the field of public utility. As such, they were financed by the Egyptian Government and the Laboratory was equipped to handle every phase of the investigations—that is, the borings, the extraction and the testing of the samples, and the levelings themselves. The Survey of Egypt assisted in some of the phases of the leveling work.

(2) It was recognized that the usual opposition of practising engineers against settlement observations of their structures might be justified in some cases. This opposition was generally due to fear of damages to the business interests concerned, should settlement observations show that the foundation design had not been fully effective. A number of special measures were necessary, therefore, to safeguard the legitimate business interests involved. These measures were:

(3) A guaranty was given that all data would be kept confidential unless the written approval of those responsible for it was first obtained. The small staff of the Laboratory was made personally responsible for the secrecy of the data in its possession. The staff was authorized, in all cases, to refuse requests for information that were inconsistent with the foregoing provisions, even if the request came officially from the Law Courts.

(4) No charges were to be made in the early stages of the investigations until the degree of accuracy of the methods used had been verified and generally acknowledged.

In this manner the initial reluctance to allow settlement observations was gradually overcome. In December, 1936 (that is, at the end of the first three years of the existence of the Laboratory) twenty-four structures were under observation, of which only three were public buildings and twenty-one were privately owned. The writer understands that this total number was doubled a year later.

RESULTS OF THE SETTLEMENT STUDIES

Conditions in the Nile Valley and Delta proved to be particularly favorable to the studies. A large number of new buildings were being erected every year. Furthermore, the compressible water-logged clay and silt deposits seldom exceeded a thickness of 30 ft and often averaged only 10 and 15 ft, being underlaid by sand which extended to considerable depths. Since the time of consolidation of a clay layer increases with the square of its thickness, the settlement studies on the relatively thin compressible layers met with in Egypt could give conclusive results much sooner than would be the case in localities with thicker deposits. The results, therefore, may be of more than purely local interest.

Naturally, only an outline of the most pertinent data is possible within the limited space of this paper. This will be realized, if one considers that a report prepared by the writer to cover, fully, the case of only one building (T) consisted of 288 pages of typescript with 72 illustrations.

The liquid and plastic limit, the natural water content, and the laterally unconfined compressive strength test were adopted as routine soil tests for descriptive and classification purposes. The advantage of these tests is that they can be performed rapidly. The liquid (w_e) and plastic (w_p) limit tests illustrate the potential properties of the basic soil material in a disturbed state. The density in the natural state is shown by the natural water content (w_n), the cohesion by the ultimate compressive strength (q_d) and the brittleness or plasticity by the strain at failure.

The subdivision of soils as "clay" or "silt" was made mainly on the basis of the liquid limit values.[2]

The observed settlements and the laboratory test data applying to the first ten buildings studied by the Laboratory are presented graphically on Figs. 1 to 12, which diagrams are intended to be self-explanatory.

Data Concerning the Final Value of Settlements.—It was found that buildings erected on clay soils could settle appreciably, the settlements increasing in direct proportion to the weight of the structure, to the thickness of the stressed clay deposit, and to the value of the compressibility coefficient of the clay type of that deposit. Driving piles into the clay by no means prevented settlements, unless the piles penetrated into the underlying sand. The intensity of stress on the clay layer beneath the pile-bearings and the thickness of that layer appeared to be the governing factors. Thus, the buildings erected on piles,

FIG. 2.—BUILDING II

embedded in the clay only, settled: Building *T* (Figs. 13 and 14), more than 10 in.; Buildings V and X (Figs. 7 and 12), more than 2 in.; and Building VIII (Figs. 9 and 10), more than 4 in. Building VIII, although only seven stories high, had about 15 ft of clay beneath its pile-bearings and settled five times as much as the heavier ten-story Building VI (in which the settlement was about 1 in., see Fig. 8) with exactly the same system, length, and loading of the piles. In the case of Building VI, the piles penetrated into sand. A five-story structure (Building VII, Fig. 9), on a lighter type of piles just touching the sand surface, had an intermediate value of settlement (slightly greater than 1 in. at one end and almost zero at the other).

Light buildings, weighing less than 1 ton per sq ft of bearing area, erected on spread footings or rafts resting on a stiff variety of local clay of a brown color (Buildings I and III, Figs. 1, 3, and 4), or on compact old silts (Building II, Fig. 2) showed small settlements of less than 1 in. The stiff brown clay and the old silt of the latter two buildings were underlaid by a thick, silty, dark clay layer about 3 ft thick.

When the stiff brown clay was underlaid by a thicker layer of a local clay, about 10 ft thick, of the same dark color but more plastic, equally light structures on spread footings or rafts settled substantially: The three-story structure (Building IV, Figs. 5 and 6) settled more than 3 in. and a light four-story villa (Building IX, Fig. 11) settled more than 6 in. In this latter case a recent silt deposit overlying the dark clay appears to have contributed to part of the settlement.

Comparison Between Load-Test Results and the Settlements of the Full-Sized Structures.—No useful relation could be established between load-test results and the settlements of full-sized structures. Thus, in the case of Building II (Fig. 2), a load test made on an area of about 10 sq ft did not show any measurable settlement under a load of 1 ton per sq ft (accuracy of reading about $\frac{1}{32}$ in.), under which load the structure settled about 1 in.

In another similar case (Building IX), the dry clay soil at the level of the foundation was so hard that no impression was left by the heel of a man spinning round on it. Obviously, a load test would have been useless under such conditions, yet the entire structure settled 6 in., due to the compression of deeper lying layers below subsoil water level.

Load tests on such layers in bore-holes gave much too high settlement values due to the inevitable loosening of the wet exposed soil surface. Under similar conditions load tests, therefore, appear inadvisable for any purposes.

In the case of Building *T*, test-piles observed for periods of several months until complete stabilization showed settlements about one-twentieth of the actual settlement of the entire structure under the same load per pile.

All piles of the buildings described in this paper are concrete piles cast in place. The steel tube driven into the ground is withdrawn and the concrete rammed with a heavy tamper. This tamper weighs about 1 500 lb for the type of piles used in Buildings V, VII, X and *T* (the usual working load allowed locally on such piles varies from 30 to 45 tons per pile). For the type of piles used in Buildings VI and VIII the tamper weighs about 4 500 lb (usual working load, 60 to 80 tons per pile).

(d) TIME-SETTLEMENT CURVE OF ZONE OF GREATEST SETTLEMENT—(EAST ENTRY)

FIG. 14.—BUILDING *T*

No load tests had been made for the other structures by the engineers in charge, since it was well known locally that, under the unit loads used in the designs, single test-piles showed negligible settlements even when embedded in clay only.

No Decrease of Settlement Was Observed as a Result of Excavation.—As recently as 1933 excavation of soil was generally advocated as a useful means of decreasing settlements, which were not supposed to begin until the weight of the superstructure had exceeded that of the soil removed. Actually, the opposite was observed (see Building II, Fig. 2). Settlements were registered immediately after loads were applied to the soil. This was probably caused by the preceding elastic swelling of the underlying moist soil in the extensive period between the end of the excavation and the beginning of construction.

Relation Between Settlements in Clays as Actually Observed and as Forecast on the Basis of Laboratory Tests.—Forecasts based on consolidation tests made on the stiff and easily swelling brown clays from the first three buildings studied gave two or three times greater settlement values than those which were actually observed. The writer then took samples of the clay to the laboratory of Charles Terzaghi, M. Am. Soc. C. E., at Vienna, Austria, and the results of the tests made there fully agreed with his own. It became quite obvious that the discrepancy could not be attributed to an individually faulty procedure, but that it was due to inadequacies of the usual standard method of testing.

Subsequently, the writer proved that the discrepancy was due to an elastic swelling of the brown clay samples during and after their removal from their position in the natural deposit.[3] An agreement between the observed coefficients and those derived by laboratory tests was reached by loading the stiff brown clay sample in the consolidation device up to the value of the natural pre-consolidation load; then unloading to the pressure corresponding to the weight of the overlying layers, loading again, and only then using the settlement coefficients from this latter branch of the compressibility pressure curve. (This pre-consolidation load, determined separately, is comparatively high due to repeated drying and swelling of the soil deposits after, and during, the flood seasons.)[4]

To compare the observed coefficients and those derived from observations on laboratory-test settlements, the writer introduced a new compression coefficient, X, which gave directly the unit compression of the layer, or of the sample, under an average unit stress:

$$X = \frac{a}{1 + e'} \times 1\,000 = \frac{s}{\Delta p \times d'} \ldots\ldots\ldots\ldots\ldots (1)$$

in which: a = compressibility coefficient, in square centimeters per gram, as determined by the standard testing procedure from the voids ratio-pressure curves; e' = initial voids ratio; s = observed settlement of layer or compression of test sample; Δp = increment of the average pressure on the layer, or on the sample; and, d' = initial thickness of the layer or of the sample.

---

[3] *Proceedings*, International Conference on Soil Mechanics and Foundation Engineering, *Paper D-1*, Vol. I, 1936.

[4] *Proceedings*, Am. Soc. C. E., October, 1937, p. 1621.

The use of Equation (1) permitted the determination of the compression coefficient, X, at any stage of loading during the laboratory compressibility test with not more than 3% or 4% error and without having to wait for the end of the test and the determination of the voids ratio of the sample.

Subsequent observations on buildings underlaid by the non-swelling plastic and weaker dark clays showed that a fairly good agreement with the observed values was obtained for these clays by the usual standard test procedure; that is, by taking the settlement coefficients from the voids ratio-pressure curve for the first loading after the test pressure had exceeded the weight of the over-burden.

Therefore, the method of taking a sample, combined with the potential capacity of a soil to swell, or to fall apart, appears to be among the factors primarily affecting the accuracy of settlement forecasts and the advisable method for the interpretation of test results. Another important factor is the original stiffness of the material because the same disturbance while removing a sample will cause a relatively greater error in the settlement forecast for a stiff clay than for a weak one.

This is a probable explanation of why most of the earlier laboratory settlement analyses gave such good agreement with the observed field values; the first investigations were made where some foundation trouble had occurred, which may be taken as an indication in itself of the presence of weak soil material. The entire question, however, takes on a totally different aspect if, as a matter of routine, one is called upon to make settlement forecasts for varying types of soil on which no previous settlement observations have been made. One often hears about the necessity of "experience" in the interpretation of soil test results. Generally, this means the number of tests and analyses performed within the four walls of a laboratory. The writer wishes to emphasize that such experience is of little value unless it is accompanied by numerous comparisons with field observations on full-scale structures. Furthermore, the experience derived from such comparisons in one locality cannot always be applied with equal success in another locality with a different geological history of its soil deposits. Hence, it follows that settlement should be studied in all localities if indications of local and general practical value are to be obtained.

The following are some average values of the compression coefficient, X, for Egyptian soils, as approximately determined from the observations on actual structures:

Material	Values of X
Plastic dark clay	0.070 to 0.030
Loosely deposited recent silt	0.070 to 0.030
Stiff brown clay	0.007
Compact old silt	0.003

These values were determined for metric linear dimensions and for stresses expressed in kilograms per square centimeter (equivalent to about 2 044 lb per sq ft); that is, $X = 0.010$, would mean that a layer 1 m thick would compress 1 cm (0.4 in.) under an average vertical unit stress of 1 kg per sq cm (14.5 lb per sq in.) throughout its entire thickness. Since this stress is approximately equal to a stress of 1 ton per sq ft, the foregoing values of X remain unchanged if the thickness of the layer is expressed in feet and the stress in tons per square foot. In all cases the underlying sand deposits were assumed to be relatively incompressible.

Efficiency of Devices for Taking "Undisturbed Samplers."—The so-called "undisturbed samplers" used had a cutting-edge of a slightly smaller diameter than the diameter of the sample-containing tube. They were similar to the so-called M.I.T. type and were found to yield reliable information as to the composition, the structure, and the approximate stiffness of the layers encountered. They preserved, intact, and revealed, important details of the layer formation none of which could be noticed if and when ordinary augers were used; the latter disturbed the structure of the soil completely and mixed its various constituents.

Thus, the "undisturbed samplers" were found to be quite efficient for purposes of soil identification and to be definitely preferable in this respect to the augers and to other more primitive methods of soil exploration. However, samplers of this type could not be considered as giving entirely undisturbed samples to the extent required for laboratory compressibility investigations, because they allowed the expansion and the swelling of the soil within the sample-containing tube. This swelling caused errors in the settlement forecasts of more than 100% and, sometimes, even 200 per cent. The narrower cutter appears to have been originally introduced by the designers of this type of sampler for the purpose of decreasing friction along the walls of the container tube, this friction having been considered as the source of greatest possible disturbance. In view of the facts observed, it appears likely that the unfavorable effects of this lateral friction have been greatly over-estimated, especially if compared to the effects of the dislocation of the structure of the soil due to lateral expansion in the container following the use of narrower cutters.

In the writer's opinion, constant-diameter samplers, at least 4 in. wide, should be tried for soils in which lateral expansion is likely to cause considerable disturbance—for instance, for pre-compressed clays of a swelling type. In such clays a state of considerable horizontal stress is likely to exist,[4] and an uninterrupted lateral confinement becomes essential for all stages during the transfer of the sample from its position in the natural deposit to the compressibility testing apparatus in the laboratory. Friction along the walls of the container is likely to be detrimental only to clays the structure of which is broken by remolding.

Not All Clays Are Unfavorably Affected by Remolding.—Compressive strength tests on numerous clay samples, both in the undisturbed and in the remolded states, showed that the dark clay samples were very unfavorably affected by remolding. This was not the case for the stiffer brown clay samples, which were only slightly affected, or not at all. The types of brown clay that were likely to swell more appeared to be least affected by remolding. The fundamental causes of this difference in behavior are not quite clear and require investigation.

Estimation of the Compressibility of Silts.—Comparison of the settlement records of Buildings II (Fig. 2), III and IV on one hand and of Building IX on the other (Fig. 11) showed that the compressibility of loose, recently deposited silts could be more than ten times as great as that of compact old silts and could produce appreciable settlements (Building IX, Fig. 11). At the same time, there are no simple means of establishing, rapidly and beforehand, whether one is dealing with a compact, or with a loose, silt. Such silts with little cohesion cannot be extracted from bore-holes below ground-water level in a really undisturbed state as required for laboratory testing. Furthermore, there is very little hope that this will ever be attained by any new system of samplers.

Nevertheless, for practical purposes, it is essential to be able to estimate the degree of compressibility of silts on new building sites. It seems to the writer that the only method which may give satisfactory results is the use of small cones slowly jacked into and through the silt or sand deposit. The pressure applied in relation to the penetration registered gives comparative empirical coefficients of the density and of the compressibility of the soil penetrated. Such methods were tried first by Professor Terzaghi in the United States and then by Dutch engineers in Holland.[5] They appear to be in need of correlation to observations and of further development, but they form what seems to be a promising innovation.

Rate of Settlement.—The rate of settlement observed was found to be in good agreement with the theoretical rate based on the permeability of the water-logged deposits stressed by the weight of the buildings when they were founded on mat or strip-footing foundations. The settlements of Building II (Fig. 2) continued for a much longer time than could be expected from the permeability tests. This continued settlement appears to be due to the constant variations of 20% of the total load twice weekly before and after the refilling of the water tank.

The settlements of light structures founded on piles resting on sand (Building VII) stopped almost immediately after construction. On the other hand, the settlements of similar but heavier structures (Building VI) continued long afterward. The causes of this latter phenomenon are not clear but may be attributed to the effect of gradual consolidation of the overlying clay and silt layers and the resulting decrease of the frictional support they temporarily provided, combined with lateral and upward flow of the stressed sand beneath their bearings.

Ground-Water Level.—The effects of ground-water level variations were found to be much less important than was generally believed. These variations depend on the Nile flood which occurs yearly at almost exactly the same periods and with very much the same amplitude. The variation in the ground-water level ranges from 1 ft to about 18 ft, according to the distance of the site from the river and to the permeability of the adjoining soil layers. Before the settlement studies were undertaken, many engineers believed that these yearly variations should be held responsible for a dislocation of the soil structure which then caused any of the settlements noticed. An examination of the time-settlement curves of the observed structures shows that this is not the case.

---

[5] *Proceedings*, International Conference on Soil Mechanics and Foundation Engineering, Rept. from the Delft Laboratory, *Paper I-I*, Vol. I, p. 181.

A pronounced effect on the time-settlement curve was observed only when the rise of the ground-water level coincided with the period of construction and when the seat of settlement was located in a deep, dark, clay layer (Buildings IV and V, Figs. 5, 6, and 7). This may be explained as follows: A rise of the ground-water level decreases, by the amount of buoyancy, the pressure component on the deep, dark clay due to the weight of the overlying layers within the height of the water rise. This dark clay has been fully consolidated under the maximum pressure from the overlying soil corresponding to the lowest ground-water level. When the water rises at the same time as the building is constructed, not all, if any, of the newly applied load of the superstructure creates stresses in the dark clay layer in excess of the previous maximum. This newly applied surface load is compensated by the decrease in the weight of the newly saturated soil layers. The rate of settlement decreases and the time-settlement curve flattens out. When, subsequently, the ground-water level falls, all the surface load of the structure erected during the period of the water rise is suddenly applied to the deeper layer of dark clay. It creates stresses in excess of the preceding maximum and a sudden and rapid increase in the rate of settlement results (Buildings IV and V, Figs. 5, 6 and 7). The same process may be repeated on a much smaller scale in succeeding years until consolidation under the effect of the load of the structure is completed.

This shows that the variations in ground-water level, in soils of the type studied, only slow down the rate of settlement during the rise of the water level and accelerate it during its fall. The final value of the settlements does not appear to be affected.

Lines of Equal Settlement.—The distribution of the settlements in plan seemed to be governed in most cases by the intensity of stress at different points of the same planes within the clay layers, which seemed, therefore, to have a horizontally uniform degree of compressibility. Lines of equal pressure, computed from the Boussinesq formulas at about two-thirds the depth of the compressible layer, or at its center, showed an agreement of shape and of relative magnitude which had to be considered as fairly good if the distributive action of the semi-rigid superstructure is taken into account as demonstrated by Buildings I (Fig. 1), III (Figs. 3 and 4), IV (Figs. 5 and 6), V (Fig. 7), X (Fig. 12), and *T* (Figs. 13 and 14). The inclination of cracks in Building VIII (Fig. 10) furnished evidence in the same direction; the horizontally uniform compressibility of the soil was also evidenced by the uniform settlement of the perfectly rigid water tower in Building II (Fig. 2), which had only a slight tilt in the direction of the prevailing winds.

The remaining two structures, Buildings VII and IX, in Figs. 9 and 11 (Building VI could be observed only on two points) unexpectedly showed irregular settlements which obviously were not governed by stress distribution but which were primarily influenced by irregularities in the compressibility of the soil. Examination of old maps showed that both buildings were situated on very recent clay, and on silt deposits of an age of less than 100 yr; they were both found to be built on sites upon which the main branch of the Nile flowed only a century ago. These recent deposits apparently had not been compacted and consolidated by repeated drying and flooding, which may account for their irregular nature.

Structures with a theoretically regular distribution of settlements were founded on older clay and silt deposits more than 800 yr old for Buildings III, IV, V, VII, X, and *T*, and deposits more than 2 000 yr for Buildings I and II. They were subjected to repeated drying and flooding during this period, which presumably had a consolidating effect on the degree of compressibility over large areas.[4]

Thus, on a total number of eleven structures discussed in this paper two were an exception to what appears to be a local rule concerning the horizontal uniformity of soil compressibility. The writer wishes to emphasize that, as yet, very little is known concerning the degree of this uniformity for different types of soil deposits in various localities. Furthermore, records from three or four, or even from a dozen, buildings in one locality cannot be considered as sufficient for the purpose of establishing rules for actual designs. Much more extensive information is required; and it can be obtained only by numerous and systematic observations in the respective localities. Until such information becomes available, foundation designs should not be based exclusively on any laws of pressure distribution but should also take into account the most unfavorable conditions that may be created by any assumed possible irregular variations in the compressibility of the soil over the area of the structure.

The settlements described in this paper were observed mostly by means of optical levelings and observation bench-marks systems devised by Professor Terzaghi,[6] several hundred of which were built in, and were found to be most satisfactory in use. Their number generally varied from ten to sixty per building, depending on its area. Bench-marks of the network of the Survey of Egypt served as datum in Cairo. The accuracy of the leveling results reported is about 0.1 in.

Damages.—The damages caused to the buildings by the settlements were found to depend mainly on the radius of curvature of the superstructure, created by its adaptation to the surface of the settlement crater. This confirmed previous investigations of the subject.[7] Only two buildings (Building *T* and VIII) suffered damages. The remainder did not show any cracks, although some settled considerably.

Thus, Building IX settled more than 6 in. with a uniform tilt to one side but without any damage. Buildings I, III, V, VII, and X had differential settlements within their small area which varied from ½ in. to 1 in.; the long Building IV had a differential settlement, between its center and its ends, of about 1.5 in.; the radius of curvature created by these differential settlements was not sufficient to crack the superstructure which deformed without external signs of damage. The maximum settlement in all these cases varied from 1 in. to 3 in.

The radius of curvature and the differential settlement of Building VIII are not known, but they must have been considerably more than those of the preceding cases in proportion to the greater maximum settlement of this building of more than 4 in.

[6] *Proceedings*, Am. Soc. C. E., September, 1937, Fig. 42(*a*) and Fig. 42(*b*), p. 1360.

[7] *The Structural Engineer*, Lond., March, 1935, p. 148.

Numerous cracks were observed, mainly in partition walls. These cracks were particularly pronounced at the corners of the building, which, in accordance with the theoretical stress distribution, should have a tendency to settle less than the center of the building, severe stresses being created thereby at the corners in the superstructure. The inclination of the cracks supported this conclusion.

The old rule-of-thumb—"strengthen the corners"—should be recalled in this connection and, if correctly interpreted, should refer only to the superstructure. Some engineers understand it as meaning that more piles should be driven or that smaller unit pressures on the soil should be used at the corners. This would have an opposite effect to the one desired, by still further increasing the difference of settlements when structures are founded on horizontally homogeneous soil.

Building *T* was also strongly cracked as a result of its large maximum settlement (10 in.) and of large differential settlements. The separation of its parts of different heights and weights, by means of expansion joints, remained totally ineffective. In this connection it should be noted that many older buildings have been damaged in Cairo when situated partly within the limits of the settlement crater of the adjoining new structures. Harmful effects of the settlement crater were noticeable even when the older structures were separated from the new ones by a free space of 6 to 12 ft.

Future Trends.—The influence of the settlement studies on the new trends of local engineering practice was considerable. In 1934, previous to beginning these studies, the height of buildings in Cairo did not exceed eight or nine stories. Some of them suffered damages, but opinions were strongly divided as to the causes. The observations of the Laboratory provided logical explanations for most of the known facts, disclosed many new ones, and dispelled many erroneous conceptions. In particular, the observations showed how strongly settlements were reduced when the loads of the structure could be transferred to deeper sand layers in a manner not endangering their state of lateral confinement. As a result, the construction of buildings (on long piles driven into the sand) of ten, twelve, and fourteen stories was started in rapid succession, and investigations for an eighteen-story building have been begun.

A few engineers now go to the other extreme and maintain that the loads of all structures should be transferred to sand by means of long piles. This view ignores considerations of economy and, therefore, is just as exaggerated as the previous local antagonism to long piles because of their excess cost.

The observations disclosed the total weight of different types of structures which could be safely supported by various successive soil layers. As a result smaller structures also benefited from these observations, greater assurance and, therefore, more justified economy becoming possible for their designs.

CONCLUSIONS

Systematic settlement observations of full-sized structures are the only reliable means for obtaining accurate data on the actual behavior of these structures and also concerning the soil on which they were erected. In many respects present-day laboratory testing methods and procedures of foundation design are still in need of correction and of development through comparisons with the results of such full-scale observations. Results obtained from observations in one locality are not necessarily valid in other localities. Therefore, such settlement studies should be undertaken in all large cities. This necessity has been recognized generally for some time, but little has been done largely because individual efforts are inadequate as compared to the scope and magnitude of the work to be performed.

The required large scale of such studies necessarily calls for a co-operative effort in their organization. To be scientifically effective these studies should be made by independent organizations not having any business connections with the structures investigated. Special guaranties to the business interests concerned are then necessary, safeguarding them against damages and thereby enlisting their co-operation. The studies in Egypt described in this paper show that such a plan is feasible and can be made successful in practice.

ACKNOWLEDGMENTS

The writer wishes to emphasize the generous support given by the Egyptian Government to the investigations described. He also wishes to express acknowledgments to the persons who have facilitated the development of these studies: To Hussein Sirry Pasha, Minister of Public Works, Egyptian Government, under whose instructions and direction the first scientific settlement investigation in Egypt was made; to Professor Terzaghi who had first proposed systematic settlement studies on full-sized structures and who, through personal contacts, contributed many valuable new ideas and inspiration; to Dr. C. Andreae, former Dean, Faculty of Engineering, Egyptian University, for his support in the organization of the new laboratories; to Dr. W. S. Hanna, Head of the Foundation Soils Research Laboratory, Egyptian University, in close collaboration with whom most of the work described was done[8] and to whose courtesy the writer is indebted for data concerning the continued settlements observed during 1937; to Dr. F. E. Relton, Professor of Mathematics, Faculty of Engineering, Egyptian University, for his help in the treatment of some mathematical problems; to Kamal Khalifa Effendi, former Research Assistant, Foundation Soils Research Laboratory, Egyptian University, for his assistance in making some of the borings, tests, and computations; and to many engineers and architects of Cairo, and of the Provinces, without whose co-operation this work could not have been successfully developed.

DISCUSSION

L. C. Wilcoxen,[9] **Assoc. M. Am. Soc. C. E.** (by letter).—The last decade of research on the problem of the stresses and strains occurring beneath foundations has done much to consolidate the current theoretical knowledge of the subject. In the matter of large non-rigid foundations on certain types of soils, for instance, it is now quite generally recognized that differential settlements must occur.

Professor Tschebotareff's contribution is to put in the record important differential settlements of a number of structures built on clay and silt. His chief conclusion is to emphasize the necessity for settlement studies in all large cities. This conclusion deserves wide recognition.

It should be understood, however, that such knowledge will be of practical value only when methods for preventing such settlements have been developed. Two methods for doing this may be used: (1) By designing the structure with sufficient rigidity to sustain the stresses induced by the unbalanced footing loads; and, (2) by treating the foundation soils in a manner to offset their movements due to compression, consolidation, and plastic flow. The former has been consciously done in at least one case.[10]

The latter could undoubtedly be done by the principle of "mudjacking," now used in raising sunken highway pavements. It may be that at some future time "mudjacking" pipes will be extended deep into the foundation soil during construction and specifications will demand that, over a period of a year or two, the contractor restrict the building settlements to certain limits.

Trent R. Dames,[11] **Jun. Am. Soc. C. E.** (by letter).—The most significant single statement in Professor Tschebotareff's paper is his conclusion that "Results obtained from observations in one locality are not necessarily valid in other localities" (see heading, "Conclusions"). This truth deserves more emphasis than it has yet received and is a fact of which any one engaged in developing general theories in the new field of Soil Mechanics should be always mindful.

Most of the new theories are the result of studies made largely on the glacial clays of Northeastern United States and Europe. Several years of effort on the part of the writer and an associate, W. W. Moore, Jun. Am. Soc. C. E., to apply many of them without modification to problems involving the foundation and embankment soils of the semi-arid regions of Southwestern United States have, in general, met with failure. Different factors assume importance; different soil tests become desirable; and different methods of analysis seem necessary.

Believing the soils of the Nile Valley to be somewhat akin in character and behavior to certain of those with which he has dealt, the writer is encouraged to enter this discussion and contribute what he has been able to learn of the behavior of soils of reasonably similar geologic background. This discussion will take the form of certain comments on the testing methods and the advancing of alternate interpretations of such settlement data as the author has found it possible to include.

[10] "Economics of Rigid Frame for Building Foundations," by Kimball R. Garland, *Engineering News-Record*, September 26, 1935, p. 427.

[11] Dames and Moore, Los Angeles, Calif.

Building I, Fig. 1.—In common with all of the other structures cited, Building I raises some questions as to testing procedure. The liquid and plastic limit tests admittedly "illustrate the potential properties of the basic soil material in a disturbed state" (see heading, "Results of the Settlement Studies"), and accordingly have value for such purposes as routine tests for highway subgrades. Their value is questionable, however, when they are applied to foundation soils which, in most cases, are used only in the undisturbed state. The use of these tests to subdivide "silt" and "clay" is novel to the United States where a division based on mechanical analysis is popular. Both methods are cumbersome and difficult of ready application; and a flexible classification based on appearance, texture, and local behavior has been found equally, if not more, effective. For foundation purposes, the effort spent on these and similar tests might better be applied to more thorough field explorations and on tests which describe the behavior of undisturbed soil under load, as, for example, shear and consolidation tests on core samples extracted from the borings.

Building II, Fig. 2.—In discussing Building II, Professor Tschebotareff, in common with nearly all modern writers, condemns the load test. In this case the accuracy of the readings taken is not sufficient to "close the case" and justify this condemnation. Admittedly the load test, as generally performed, clouds the picture and frequently breeds false security, but when properly conducted, it is a valuable aid to the foundation engineer. In the case in question, if the test area and water tower can be assumed to settle roughly in proportion to their diameter (no data on which to base an opinion being available), the settlement of the test area during the probable time of test (not stated) very possibly would not have been detected.

To get results from a load test, the soil and location at which it is made must be chosen carefully, not necessarily at foundation depth. The increments of load should be known to within 5%; the settlements should be measured (for test areas of, say, 2 sq ft to 10 sq ft) to 0.001 in.; and sufficient time should be allowed for the test footing under each increment of loading to achieve equilibrium. The shape of the curve is frequently of more importance than the magnitude of the settlements, and it indicates to the engineer who is familiar with its interpretation many characteristics that no laboratory test will describe.

The author describes the errors in computed settlements resulting from an analysis dependent on compression tests made on swelling clays and silts that are sampled with difficulty. The load test can be, and has been, used to obtain an experimental ratio by which the settlement computations may be multiplied to predict the settlements of a structure more accurately. (The adjustment of settlement computations by means of a ratio obtained in this manner frequently formed part of the settlement computations reported by Mr. Moore and the writer.)[12]

---

[12] *Civil Engineering*, January, 1939, p. 41.

The record of Building II is used to justify the statement: "No Decrease of Settlement Was Observed as a Result of Excavation" (see heading, "Results of Settlement Studies"). It is true that Building II has settled about 1 in. during the three years of record, but no data are introduced to disprove the logical premise that this structure would have settled more than 1 in. if founded at, or near, the surface of the ground. Comparison with the only other building founded on soil 2 000 yr old (Building I) is futile because, in this case also, moderate excavation was resorted to and more particularly the soil had undoubtedly been pre-stressed by the considerable load of the old water tank, the bottom of which was utilized for the foundation of the new structure.

Of the buildings on soil 800 yr old, Building III is on spread footings and is not comparable as to load over an extended area. The spread footings of Building IV so nearly cover the area as to approach a mat in behavior. A similar sequence of soils both as to classification and description by the physical tests given exists under both of Sites II and IV. In each case the sand is at 40 ft; and the unit loads on the foundations are the same. The settlements of Building IV, founded near the ground surface, are more than three times those of Building II, founded at a depth of 18 ft, and occur during a somewhat shorter period of record.

Another mat of similar size, that of Building IX, founded near the surface and underlain by the same quantity of compressible soil as Building II, settled six times as much under one-half the unit load, or a factor of 12 to 1. The uppermost silt underlying Building IX is stated to be about 100 yr old, and the lower soils are of more recent age than those under Building II. However, in the absence of tests of the compressibility of these recent soils, it would seem unwarranted to assume an average compressibility coefficient in one case of twelve times the other, particularly when the proof of the case against excavation as a means of reducing settlements rests on such an assumption.

Building III, Figs. 3 and 4.—The settlement of Building III at an undiminished rate from the middle of 1935 through 1937 would seem to warrant an attempt at explanation. On many California soils such a settlement curve would probably indicate that incipient shearing failure has occurred, and that a moderate degree of plastic flow of the over-loaded clay from beneath the spread foundations of this structure is occurring.

Building IV, Figs. 5 and 6.—This building was discussed under Building II as an example of lack of excavation. As in Building III, the continued, undiminished rate of settlement since the middle of 1936 could be interpreted as caused, at least in part, by shearing failure and the resulting plastic flow of over-loaded soil from beneath the foundations of this building.

Building T, Figs. 13 and 14.—For convenience of discussion, Building *T* will be considered before any of the other buildings on pile foundations. The writer is unfamiliar with the type of piling used in these Egyptian structures as it is seldom, if ever, used on the Pacific Coast of the United States. For this reason he will have to assume that the diameters of these piles (which are not given by the author) are nearly comparable to the diameters of the driven or cast-in-place piles of his experience.

The individual piles of all of the buildings described in this paper seem more heavily loaded than the soil conditions warrant. Tests of the shearing strength of the soil which would permit a determination of the load at which individual piles would begin to penetrate the soil about them are apparently not available. The load tests presented in Fig. 14(*c*), however, most certainly indicate that this penetration is occurring at loads in excess of 40 tons, possibly even at lower loads, the settlement scale being too small to describe the shape of the curve below this point. On several occasions the writer has found that the point at which the curve of a pile load test departs from an approximate straight line agrees remarkably well with a determination based on a summation of the circumferential area of the pile times the shearing strength of the soil penetrated and the bearing on the pile point. The spacing of the piles when grouped in clusters is not stated, but if it is at all similar to the practice in California they are so close that the circumference of the group times the shearing strength of the soil will give a lower value than 40 tons per pile for the load at which penetration of the group occurs.

Additional support for the belief that the settlement of Building *T* has been largely the result of individual pile failure and not due to the compression of the 10 ft of dark clay between the pile points and the sand is furnished by the following reasoning: This dark clay is stated to be more than 800 yr old and to have been subjected to compaction and consolidation by the repeated drying and flooding by the River Nile through the intervening centuries. Accordingly, it is reasonable to assume, from the tabulation following Equation (1), that the compression coefficient for stiff brown clay (0.007) is reasonably representative of this material and not the value given for plastic dark clay (0.070), which, in the absence of test data on either Fig. 13 or 14, was presumably obtained by working backward from the settlements of the structure. Using the value of the compression coefficient (0.007) the maximum load of 17 tons per sq m (= 1.6 tons per sq ft), and the thickness of the dark clay (10 ft), the compression in the clay layer becomes $1\frac{3}{8}$ in. leaving the remainder of the 10 in. of settlement recorded to date to be attributed to individual or group pile penetration.

Building V, Fig. 7.—The piles in Building V are more moderately loaded than those in Building *T*, but in view of the 800-yr age of the soils beneath the piling and the magnitude of the settlement (2.5 in.) to the middle of 1937, about one-half the present settlement may need to be explained by penetration of the piling. If this is true, this building may continue to settle appreciably for some years to come.

Building VI, Fig. 8.—The average load of 64 tons per pile seems excessive, even when the 6-ft to 8-ft penetration of the 27-ft piles into the very fine sand is considered. The shape of the time-settlement curve and its failure to quickly become horizontally asymptotic would indicate that shearing failure and flow of the soil is occurring. The attribution of any appreciable part of this settlement to the effect of gradual consolidation of the overlying clay and silt layers and the resulting decrease of the frictional support they temporarily provided does not seem reasonable. In view of its shearing rigidity being necessarily considerably less than that of the sand, the brown silt layer could scarcely have been carrying any large proportion of the total load at any time; and, in the three years of record, this 12-ft or 13-ft layer could scarcely have consolidated under the weight of the superimposed silt and "old" fill as much as the 1.25 in. settlement recorded.

Lacking data as to the occupancy and location of this building the writer would hazard a guess that the continuation of the settlements may be aided by elevator or traffic vibrations transmitted by the piling to the over-stressed sand. Similar examples have come to his notice in the case of buildings founded on sand which has been over-loaded by the foundations. A building occupied by a publishing establishment showed visible distress only in the vicinity of a heavy press. In some buildings cracks have been observed only in the bays immediately adjacent to the elevator shafts.

Building VII, Fig. 9.—Inasmuch as the piles seem primarily end-bearing piles and apparently would not receive any large proportion of their support from the less than 100-yr old silt and clay deposits above the sand, the pronounced irregularities of settlement cannot be primarily the result of irregularities in the compressibility of the soil. Vibrations are again hazarded as a possible explanation. Included in this category must be considered any vibrations that occur during the placing of the piling and during construction. For example, the state of stress in the compacted and densified sand under the first piles to be placed might have been released by vibrations occasioned during the placing of subsequent piles. The remaining three buildings are similar to those previously discussed.

Although the writer has taken a different point of view than the author and has taken every opportunity to present and advance a different interpretation of the data, he appreciates, thoroughly, having had the opportunity to study such a comprehensive paper and believes that Professor Tschebotareff deserves the highest praise for having so completely made the results of his observations available to the profession.

Edwin J. Beugler,[13] M. Am. Soc. C. E. (by letter).—A distinct service has been performed by Professor Tschebotareff in presenting unusually complete data as to settlements occurring with various types of foundations on sedimentary formations under an imposed unit loading. The data, largely in graphic form, afford a clear picture of cause and effect. Several types of footings are shown with a diversity of soils and intermittent ground-water levels.

Of prime importance is a distinction between the relative settlement during construction and that occurring later under the completed structure. The former is due to compression, shrinkage, and more or less elastic reaction, and ceases when the building is finished, or shortly thereafter, provided the unit loading of the soil has been selected conservatively. Conversely, continued progressive settlement of the completed structure indicates over-loading and ultimate failure. If the rate of progressive settlement is decreasing it is possible, in most cases, to predict the time of ultimate cessation.

The time-settlement curves given in Fig. 9 (Building VII) shows a well-designed foundation for the situation involved, and illustrates the foregoing statements. Loading as construction proceeded caused a maximum compression of about 1.3 in. After the structure was completed no appreciable settlement occurred. The action may be likened to placing a load on a spring scale which is compressed proportionately to the applied load and thereafter remains stationary under a constant load.

---

[13] Cons. Engr., Cheshire, Conn.

Much of the confusing information concerning settlements has been due to overlooking this important phase. For example, the progress report of the Special Committee on Earths and Foundations, presented in 1933, pictures a settlement record of the Washington Monument[14] from 1879 to that date, amounting to 5.5 in. and "probably still slowly settling." Analysis of the record shows that 4.5 in. of this settlement occurred between 1879 and 1885 during construction, which added 400 ft to the height of the shaft as completed in 1885. The remaining settlement of only 1 in. under a constant load during nearly 50 yr, it must be granted, indicates a fairly stable structure, and a monument to the engineers who so skillfully underpinned the old foundation, as well as a monument to the hero of 1776.

The self-explanatory diagrams may enable one to determine offhand the cause for failure or inadequacy. From the time-settlement curves for the various buildings it may be concluded that over-loading is responsible for most of the progressive settlement. Some was due to the fact that piles did not penetrate to firm material, or that they failed to distribute the load in other respects.

The author states that no decrease of settlement was observed as a result of excavation (heading "Results of the Settlement Studies"). This was doubtless true for the case cited. On the other hand, one instance in the writer's experience is worthy of note. In 1919 an important structure was settling progressively at one end and remaining stationary at the other. It was supported on piles driven to refusal. Rock was 40 ft below grade at the undisturbed section and 170 ft below with intervening sedimentary strata, including a band of soft clay, at the depressed end. There were no cracks in the structure. The settlement of 18 in. was stopped by excavating earth within and around the building, the outside area being replaced by light reinforced cellular construction. The load on the area was reduced about one-third before the settlement ceased. The structure has since remained stationary.

The author states that no useful relation could be established between load-test results and the settlement of full-sized structures. The meager data given regarding the method of making such tests precludes comment as to other methods and deductions therefrom. Reference to this and other matters has been made by the writer elsewhere.[15]

W. S. HANNA,[16] ESQ. (by letter).—The method applied to Buildings I, II, and III in this paper gave a fairly satisfactory forecast of settlements, based on laboratory tests (see heading, "Results of the Settlement Studies: Relation Between Settlements in Clays as Actually Observed and as Forecast on the Basis of Laboratory Tests"). Briefly, the process involves loading the sample until it has reached its preconsolidation pressure, and then unloading it until it sustains only the weight of the upper layers. The resulting branch of the compression curve is taken as the basis for computing the calculated settlement forecast.

[16] Head of Soil Mechanics and Foundation Research Laboratory, Egyptian Univ., Cairo, Egypt.

Buildings investigated subsequently by the Laboratory at Egyptian University gave different results; in a few cases the predicted settlements were less than the actual settlements; whereas in the cases reported by the author the forecast settlements were higher than the actual. Professor Tschebotareff tried several methods, of which the foregoing seemed to fit most closely. Contradictory results observed subsequently led the writer to investigate the entire problem again. There is no doubt that the samples of brown clay expand while being removed. On the other hand, it seems improbable that the resulting strains can be avoided by the process described in the paper, which amounts to remaking the sample in the odometer until a state similar to its condition in the soil is reached. This procedure ignores all the plastic strains produced and the effect of confining the sample in the odometer. Furthermore, there is considerable difference in the compression curve of undisturbed local clays and the curves derived from clay samples, and this is observed in both the swelling and the non-swelling types. Therefore, the writer undertook to study the entire problem from a new angle. Preliminary results of these studies indicate that the author's statement that the method described in the paper has proved a success cannot be considered final.

The writer does not agree with Professor Tschebotareff's conclusions regarding the pronounced effect on some time-settlement curves of the annual rise and fall of ground-water level as a result of the flood. He states (see heading "Results of the Settlement Studies: Ground-Water Level") that "A pronounced effect on the time-settlement curve [due to the variation of the subsoil water level during the yearly flood season] was observed only when the rise of the ground-water level coincided with the period of construction and when the seat of settlement was located in a deep, dark, clay layer" (words in brackets are by the writer). On the contrary, the writer believes that the effect is mainly due to the upper layers traversed by the rising water, which consists generally of the brown clay. The reasons are briefly as follows:

(*a*) The decrease of pressure on the deep, dark clay, caused by the buoyancy of the upper layers affected by the rising water, is quite small. It is true that buoyancy decreases the specific weight of the layer through which the water flows; but the specific weight is increased as a result of the increase in the water content. The actual weight of 1 cu m of brown clay, below normal ground-water level, is 1.65 tons; but it weighs 2.08 tons during the flood season, when weighed after it has been disturbed. Except in its undisturbed position in the immediate vicinity of the river, the maximum rise is 2 m. In such cases, therefore, the maximum reduction in pressure as a result of buoyancy is $2 \times 0.057 = 0.114$ kg per sq cm (233 lb per sq ft). When part of the period of construction coincides with the flood period, the increase in pressure due to the weight of the buildings ranges from 0.4 to 0.8 kg per sq cm of the area of the building (817 to 1 635 lb per sq ft). Of course, these values do not represent the component of the increased pressure on the deep layers, but they furnish a basis of comparison. In computing the buoyancy, furthermore, full upward hydrostatic pressure has been assumed, which is impossible in the case of plastic clay layers.

(*b*) In most cases the layers through which the flood water passes are the brown clays, which are either stiff or soft and silty. The stiff clay, if permeable, exhibits strong swelling tendencies when placed in the odometer. This is not elastic swelling, because the sample has had sufficient freedom to swell completely during the shaping and after leaving the sampler. It is due to the absorption of water from the porous stone when it is placed in the odometer.

The writer conducted several tests to study the effect of the swelling due to absorption. The pressures required to return the 12-mm sample to normal, when swelling occurs under the weight of the piston alone, vary between 0.18 and 0.30 kg per sq cm (368 and 613 lb per sq ft, respectively). Therefore, it is safe to assume that, where such brown clays are reached by rising water, the swelling of these layers reduces the pressure on the layer above them and, probably, to a slight degree, on the lower layers (this is a mere assumption). When the water recedes and the soil retains its normal water content, the swelling resistance disappears and the resultant pressure on the upper layers is suddenly increased. This explains the reduced rate of the time-settlement curve during the rise, and the increased rate, during the fall, of water level. Furthermore, it is a known fact that most old houses settle soon after the ground-water level beneath them has been lowered. The slight movement of the building when it responds to the swelling of the soil seems sufficient to crack its walls. Most of these houses have bearing pressures not exceeding 0.3 kg per sq cm (613 lb per sq ft) and the mortar, which was originally of a poor quality, has deteriorated with age.

As compared with dark clays the brown clays are relatively little affected by remolding when tested in the unconfined state (see heading "Results of the Settlement Studies: Not All Clays Are Unfavorably Affected by Remolding"); and brown clays, of the same origin as those found in the interior, have been found near the sea. This brown clay is very remoldable. Furthermore, extremely silty types of it, which are very stiff in the natural state, crumble under the smallest pressure when remolded; and, both the brown and dark clays are strongly affected by remolding when tested in the confined state, a case which is not observed in samples of brown and dark clays found in the interior. It would be quite interesting, therefore, to learn whether similar behavior in clays deposited under saline water has been observed elsewhere.

The writer agrees entirely with the author's statement (see "Results of the Settlement Studies: Efficiency of Devices for Taking 'Undisturbed Samplers' ") that in the swelling types of clays, uninterrupted lateral confinement becomes essential for all stages until it is placed in the odometer. Some time ago the writer experimented with a special ring that can be fitted both to the samples and to the odometer, so that the soil sample can be tested without removing it from the sampler. It was tested in connection with the different samplers and also was used alone to extract the sample after the hole was cleared directly under the bore tubes. Some interesting, and some rather contradictory, results were obtained. On the whole, however, the effect of lateral swelling seemed to be about 100% in the clays most seriously affected. This means that the investigator must search elsewhere for the explanations of the difference (in some cases of more than 100%) between the actual values of settlements and the values based on the odometer tests.

D. P. KRYNINE,[17] M. AM. SOC. C. E. (by letter).—The importance of settlement observations on full-sized structures has often been emphasized in technical literature. The paper by Professor Tschebotareff is a valuable contribution in this respect.

Two Cases of Settlement Discussed.—Before examining the interesting collection of settlement contour lines presented by Professor Tschebotareff, the writer wishes to express some general thoughts on the shape of such lines. Two different cases will be distinguished: Case A, in which the structure, or the tips of the piles supporting it, reaches the top (or nearly the top) of a compressible layer; and Case B, in which the compressible layer is at a considerable depth. Most of the structures discussed in the paper are examples of Case A.

Settlement in Case A.—When the compressible layer is more or less uniform and is sufficiently thick, it appears first that it may be considered as a semi-infinite, elastically isotropic body. In such a case settlements could be computed according to elastic theories:

$$s_0 = \frac{P}{r} \frac{1 - \mu^2}{\pi E} \quad \text{.......................(2)}$$

in which: s_0 = settlement at a given point; P = load; r = horizontal distance from the load P to the given point; μ = Poisson's ratio; and E = modulus of elasticity of the earth material.

However, it is difficult, and perhaps impossible, to determine the elastic constants of the given earth material in the field. Furthermore, the settlement of a clay deposit is due also to the load squeezing moisture from its pores so that the actual settlement is many times greater than the computed value. An assumption can be made, however, which is of the same order of accuracy as assumptions made in the theory of consolidation; namely, that the actual value of the settlement to be expected is proportional to the value of s_0, as computed using Equation (2). In other words, the settlement is proportional to the ratio $\frac{P}{r}$. In Equation (2) substituting

$$C = \frac{1 - \mu^2}{\pi E} \quad \text{.......................(3)}$$

relative values of the expected settlement can be computed easily. Let s_0' and s_0'' represent settlements at two different points of the ground surface, as caused by load P; and, let r' and r'' represent respective horizontal distances of these points from load P. Then:

---

[17] Research Associate in Soil Mechanics, Dept. of Civ. Eng., Yale Univ., New Haven, Conn.

$$s_0' = C \frac{P}{r'} \qquad (4a)$$

and

$$s_0'' = C \frac{P}{r''} \qquad (4b)$$

from which:

$$s_0' : s_0'' = r'' : r' \qquad (5)$$

that is, elastic settlements at two different points of the ground surface are inversely proportional to their horizontal distances from the load. Relative values of elastic settlement at any point of the ground surface, as caused by a uniformly loaded area of arbitrary shape, can be computed, even in complicated cases, by using the method of graphic integration. W. Steinbrenner has given analytical formulas and has prepared tables of such settlements in the simplest case of rectangular loaded areas.[18]

It should be noted, however, that Professor Terzaghi advises that the settlement of shallow layers (such as described under "Case A") be computed in the same manner as that of deep layers[19]; and Professor Tschebotareff follows that procedure.

Settlement in Case B.—Should the compressible layer occur at a considerable depth, its consolidation is attributed to the action of the vertical pressure, p_z, which is computed using the well-known Boussinesq formula. The distribution of the vertical pressure at the top surface, $a\ a_0\ a'$, of the compressible layer is given in the form of a curve, $a\ a_0\ a'$, in Fig. 15. A similar distribution occurs along any other horizontal plane of the compressible layer; as, for instance, at the bottom (Section $b\ b'$, Fig. 15). All ordinates of the distribution curve traced at the bottom of the layer would be smaller than those at the top. Consider a vertical section ($o\ r\ u\ m\ n$, Fig. 15) of the earth mass. Plotting vertical pressures, p_z, at different depths of this section as horizontal ordinates, a curve, $o\ s\ w\ p\ q$, would be obtained. The shaded area, $m\ p\ q\ n$, multiplied by a coefficient depending on the compressibility of the layer in question ("specific loss of moisture" as discussed hereafter), furnishes the value of the final settlement at Point o. It is assumed in this connection that a column of earth such as $o\ m$ or $t\ t'$ settles independently of the remainder of the earth mass, and that, in sinking down, it does not undergo any change of volume or shape. In other words, soil deformations above the compressible layer $a\ a'\ b'\ b$, Fig. 15, are neglected. The soil above the compressible layer is thus assumed to be deprived of shearing resistance.

It should be noted that the Boussinesq formula for the vertical pressure does not contain the elastic constants E and μ; hence, it is valid for any homogeneous, elastically isotropic material. Were the entire mass made of clay, or of steel, or of some other homogeneous material, which could be considered as elastically isotropic, Boussinesq's formula for the vertical pressure would furnish fairly satisfactory results, regardless of the type of material. Its use becomes questionable, however, in the case of a compressible layer, since there is discontinuity at the top of the latter, and the material is no longer homogeneous.[20] This phenomenon has been explained also by the "bridging (or arching) effect" of a sand or gravel layer which overlies a compressible clay layer. According to the latter view, the load applied at the earth's surface is spread by the intermediate sand or gravel layer so that the magnitude of the stresses and their distribution in the lower compressible layer are thus modified.

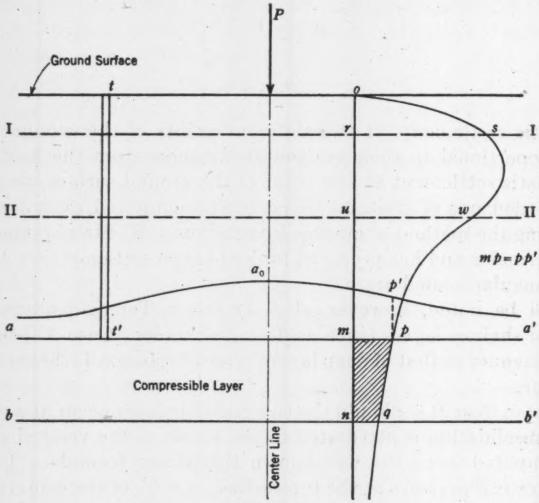

FIG. 15

Settlement at a Considerable Depth as Caused by a Loaded Area.—According to Saint Venant's principle, stresses at a point within a body remote from the surface where a system of forces is applied are practically the same as those caused by the resultant of that system. Hence, stresses and strains in a deep compressible layer are practically the same as those caused by the resultant P of the forces acting on that area. It is evident that stresses thrown to the compressible layer in question should be practically symmetrical with respect to the vertical line of action of force, P. In other words, the set of lines of equal settlements at the earth's surface should approach a set of concentric circles if the seat of settlement is at a considerable depth. Professor Tschebotareff's contour lines are far from being concentric circles, however; this is because, in reality, the settlements in question have their seats in rather shallow layers.

Influence of the Rigidity of the Superstructure.—Professor Tschebotareff presents interesting comparisons between theoretical settlements in the case of rigid and non-rigid (flexible) superstructure, or more accurately, of the rigid and non-rigid base of the superstructure. Quite striking is the case of

---

[20] *Transactions*, Am. Soc. C. E., Vol. 103 (1938), p. 885.

Fig. 1 in which lines of actual settlement follow rather closely the lines of equal pressure shown in that figure, which is assumed to be rigid. It is important to notice that, in this case, the seat of settlement is in a rather shallow layer. The writer believes that the influence of rigidity on the pressure distribution at a horizontal plane decreases with the depth. This is in accord with Saint Venant's principle since at a greater depth the values of the stresses are controlled merely by the total weight of the entire structure (assuming that this weight is the same in the case of both rigid and non-rigid superstructure). In the same degree, the size of a rigid structure may have a certain influence on the settlement; apparently, the larger the structure, the less will be the influence of the rigidity on the stresses underneath the central part of that structure. In the limiting case in which both rigid and non-rigid structures are infinitely long and infinitely wide, there should be no difference whatsoever between a rigid and a non-rigid structure, since in such a case the value of the settlement would depend entirely on the properties of the earth material.

Depth at Which the Vertical Pressure Should Be Computed.—Professor Tschebotareff computes the vertical pressure "at approximately two-thirds the depth of the compressible layer" (in some occasions one-half that depth).

This approximation is not always warranted. In the case of a deep layer, such as that bounded by Plane $a\,a'$ (Fig. 15) and Plane $b\,b'$, the area controlling the settlement is $m\,p\,q\,n$, and its average ordinate is approximately at the middle of the layer. Should the layer be close to the earth's surface (for instance, the layer bounded by Planes I–I and II–II) the situation is entirely different; and the average ordinate may or may not be at the middle or at two-thirds of the height of area $r\,s\,w\,u$. Professor Tschebotareff's assumption is practically correct in the case of a shallow layer between the ground surface and Plane I–I (Fig. 15).

Coefficient of Compressibility, X.—Professor Tschebotareff is to be commended for introducing the coefficient of compressibility, X, as defined by Equation (1), and in comparing the laboratory value of this coefficient with the corresponding field value. Since the value of $\frac{a}{1 + e'}$ in Equation (1) is the reciprocal of what is analogous to the modulus of elasticity, that value is measured by a reciprocal of stress (in square centimeters per gram, as Professor Tschebotareff states). The second part of Equation (1) proves it, since $\frac{s}{d'}$ is a strain and Δp is a stress, so that X is a strain-stress ratio. For practical purposes it is convenient, however, to express X in units of length as is done by the author as well as by Terzaghi and Fröhlich.[21] The latter expresses the value of $v = \frac{a}{1 + e'}$ as "specific loss of moisture." If a prism of arbitrary horizontal cross-section is imagined to be cut from a compressible layer 1 m thick, and is still confined laterally and subjected to the action of a compressive stress of 1 gram per cm², v will be the height (in meters) of the column of water squeezed from that prism. If the stress is increased 1 000 times and equals 1 kg per cm² (1 ton per sq ft, approximately), the value of *v* is to be multiplied by 1 000, thus becoming Professor Tschebotareff's coefficient:

---

[21] "Theorie der Setzungen von Tonschichten," by Charles Terzaghi and O. K. Fröhlich, Leipzig and Vienna (1936), p. 24 *et seq.*

$$X = \frac{a}{1 + e'} \times 1\,000 \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

The value of X is still in meters; for instance, $X = 0.010$ m, as in Professor Tschebotareff's example tabulated in the text following Equation (1). The expression "specific loss of moisture" has been introduced as an analogy of the conception "specific heat" in physics and thermodynamics.

Quite ingeniously, Professor Tschebotareff has shown that it is not necessary to make a complete consolidation test if an error of 3% or 4% is tolerable. He thus obtains the valuable part of the test without wasting time and energy on non-essential phases of it.

Conclusions.—In the five years, 1934 to 1939, the literature on soil mechanics has been substantially increased by observations of settlement in different parts of the world. To the original observations in Western Europe and the eastern sections of the United States, observations in the Western United States, in the South (Texas and Louisiana), in Mexico, and now in Egypt, are added. Numerous interesting observations in Russia have been published in that language. All this material needs to be digested and classified. The writer believes that a new chapter in the study of soil mechanics is opening which may be called "geography of settlement observations," and that its adequate development is of great importance for foundation engineers.

GREGORY P. TSCHEBOTAREFF,[22] M. AM. SOC. C. E. (by letter)—The contributions made to the problem of settlement studies by the discussers of the paper are appreciated sincerely. The writer is glad to have the opportunity to clarify the problems discussed by stressing some of the data contained in the plans and diagrams, which were overlooked by the discussers, and by supplying additional data concerning the studies reported in the paper in a necessarily condensed and summarized form.

The Design of Structures to Withstand Differential Settlements Is Quite Practicable.—It was gratifying to note that Mr. Wilcoxen recommended wide recognition of the writer's chief conclusion concerning the necessity for settlement studies in all large cities. Mr. Wilcoxen suggests that two methods may be "developed" for the purpose of preventing detrimental effects of differential settlements.

The first of these two methods—that is, a suitable preventive design of the structure—is quite practicable at present. However, it does not always imply merely the provision of sufficient rigidity for the combined superstructure and foundation. In some special cases (such as steel tank foundations) a flexible foundation, matching the flexible superstructure, will give better results.[23]

Further, a suitable architectural design is important for all buildings on soft ground. The omission of high towers and low annexes, and the provision of deep basements, as well as other measures permitting the use of reinforced concrete walls several stories high, are among the features that help to equalize settlements.

---

[22] Asst. Prof., Civ. Eng., School of Eng., Princeton Univ., Princeton, N. J.; formerly, Research Engr., Foundation Soils Research Laboratory, Egyptian Univ., Cairo, Egypt.

[23] "Progress Report of Special Committee on Earths and Foundations," *Proceedings*, Am. Soc. C. E., May, 1933, p. 812.

The construction procedure followed may also be of importance. For instance, if a low annex is essential, settlement stresses in its framework may be reduced considerably by postponing the erection of the annex as long as possible. Its simultaneous construction with the upper, and not the lower, stories of the adjoining high part of the building may suffice in the numerous cases when a large percentage of the final settlement will have occurred during construction.

The practical importance of the knowledge of the settlements to be expected is not limited to cases of excessive settlement. Any definite knowledge in the matter reduces guesswork and permits more economical and rational designs.

"Mudjacking" of Compressible Soils for the Purpose of Increasing Their Resistance Is Impracticable.—Mr. Wilcoxen further suggests treating foundation soils to prevent differential settlements by using "mudjacking" pipes extended deep into the foundation soil.

This suggestion does not appear at all promising. "Mudjacking," as successfully used in highway construction, serves to raise sunken pavements by injecting, under pressure, a soil-water slurry between the relatively light concrete pavement slab and the surface of the soil. The entire operation is similar in principle to the frequent and successful use of jacks for the purpose of raising a bridge bearing and then wedging it up the distance that the pier beneath it had settled.

The problem is different, however, if one tries to inject anything into the ground itself for the purpose of preventing its compression or deformation under load. The injected liquid tends to flow in the direction of least resistance. This circumstance may be utilized to fill, with cement grout, or chemicals, cracks in rocks or in dry clays, or cavities beneath foundations in order to prevent seepage. In plastic materials, and even in sands, this very circumstance means that only some irregularly distributed and more permeable, but not necessarily more compressible, veins of the soil may be given rock-like hardness. Obviously, this is of no advantage, and may be directly detrimental where differential settlements are concerned.

In 1932 a European firm specializing in this kind of work attempted to consolidate the weak, dark clay beneath the pile bearings of Building *T* by successively injecting into that clay separate solutions of two different chemicals. This attempt failed, although the two solutions formed a "gel" when coming into contact with each other and gave a rock-like hardness to that clay when mechanically mixed with it in the laboratory. A further test was made with the chemical-consolidation method in a dry, silty sand layer. A subsequent excavation of an injection revealed what resembled an inverted sandstone tree. The trunk was only about 10 in. in diameter. Four or five branches stretched out horizontally, one of the branches being almost 5 ft long. Therefore, in order to create a continuous mass of solidified, silty sand, the injection pipes would have to be driven at not more than 10 in., center to center, and much closer in less pervious soils. This is obviously impracticable in most cases.

The General Principles of Soil Mechanics Are Valid in Any Locality.—Mr. Dames considers the author's conclusion that "Results obtained from observations in one locality are not necessarily valid in other localities" to be the most significant single statement of the paper. The writer agrees that this conclusion is very important and should be emphasized. At the same time he wishes, emphatically, to warn against the inference contained in further statements by Mr. Dames that most of the new soil mechanics theories (unspecified) are seldom valid except for glacial clays of Northeastern United States and Europe.

The general principles of soil mechanics are valid everywhere. It is a frequent but regrettable practice to apply a theory, superficially, to local conditions which do not correspond to its underlying assumptions. After the inevitable failure the entire theory is then often proclaimed invalid without further analysis. The writer cannot judge the nature of the "different" soil tests and methods advocated for Southwestern United States by Mr. Dames since their nature is not specified; but whatever their nature or their merits they cannot warrent arbitrarily ignoring conclusions based on a theoretical analysis of observations. This is especially true when the observations are made under field conditions closely approximating the assumptions on which a widely known theory[24] is based, whereby both the field and the laboratory results agree as well as agreement can be expected, theoretically. To illustrate these remarks the writer will examine some of the discussions of the time-settlement curves, which ignored the effect of the permeability of a stressed clay layer on the rate of its compression.

The Rate of Settlement of a Fully Saturated Clay Layer Is Governed Primarily by Its Permeability and Thickness.—In discussing Building IV, Figs. 5 and 6, Mr. Dames states: "* * * the continued, undiminished rate of settlement since the middle of 1936 could be interpreted as caused, at least in part, by shearing failure and the resulting plastic flow of over-loaded soil from beneath the foundations of this building." An examination of Fig. 6 shows that the rate of settlement had not been constant since the middle of 1936. Seasonal variations of subsoil water levels provide definite breaks in the time-settlement curve; the rate of settlement is slowest when the subsoil water level is highest, almost reaching to the elevation of the foundations; then the rate of settlement increases as the subsoil water level drops about 14 ft. The reverse should have been the case if Mr. Dames' interpretation were correct, because a decrease in the moisture of a cohesive clay increases its cohesion and therefore its shearing strength, simultaneously decreasing its tendency to undergo plastic deformations. In the case of Building IV the borings were made at the time of lowest water level and the chart of laboratory test results (Fig. 6) shows that at that time the clay soil immediately beneath the foundation was very stiff and was of a definitely brittle type least likely to undergo plastic deformations.

Thus all available facts contradict the aforementioned interpretation by Mr. Dames. On the other hand, computations based on the rate of compression of the deeper lying, soft, dark clay layer following the expulsion of surplus moisture show that settlements of Building IV due to that cause were still to be expected during 1936–1937. This therefore provides reasonable explanation for them. Nevertheless, the writer does not deny that plastic shearing deformations may have some influence on the rate of settlement and has recognized this fact in the past.[24] On deep lying, fully water-logged, clay soils, however, this cause is likely to be of any relative importance only after the settlements due to the expulsion of surplus moisture have slowed down almost entirely. The results of further-continued observations may disclose whether this is the case for any of the buildings under discussion. The only case reported in this paper where plastic shearing deformations may be at all reasonably assumed to be of importance thus far is Building VI (see Fig. 8). The writer stated that the cause of the continued settlement was not clear and suggested tentatively that it might be attributed to the effect of gradual consolidation of the overlying silt layers and to the resulting decrease in the frictional support they temporarily provided. Mr. Dames misunderstood this to mean that the silt layer was believed to be consolidating under its own weight. Undoubtedly this is most unlikely. The writer referred to consolidation under pressures from the building transmitted by the footings which capped the piles and by the relatively high skin friction of the piles themselves.

---

[24] "Factors Affecting the Accuracy of Settlement Rate Forecasts," by Gregory P. Tschebotareff, *Proceedings*, 18th Annual Meeting, Highway Research Board, Part II, December, 1938.

The writer agrees that gradual plastic shearing deformations of both the silt and the sand (as suggested by Mr. Dames) may have been equally or even more important than consolidation in this one case of Building VI. Furthermore, the possibility of some small, plastic, shearing deformations is not entirely excluded in the cases of Buildings II and III, but a much more likely explanation is provided by the action of the repeated variations of the live load. The total pressure on the ground surface beneath Building II is decreased by 20% and then increased by the same amount twice every week. A similar but daily fluctuation of about 10% of the total pressure on the ground surface occurred beneath Building III in the zone of Points 26 and 28 under the balcony of that movie house. It was only these points which showed any noticeable continuation of the settlements, whereas Point 1, with the same unit pressure on the surface of the ground, but so located that the effect of the live load variations would be relatively small, showed only a negligible continued settlement of about $\frac{1}{16}$ in. during 1.5 years.

Mr. Dames mentions vibrations as a possible cause for continued settlements; but they could not have been of importance in this case. No machinery was present. None of the lifts of Building *T* functioned until 1934, none of them was located in the zone of continued greatest settlements, and no cracks were to be found near them. Street-car lines and an otherwise busy thoroughfare passed next to Building *T*; but this thoroughfare ran east and west along the north side of the building, which side settled slightly less than the south side of the building (Fig. 13) where it adjoined a small street with much less traffic and no street-car lines. The reverse should have been the case if traffic vibrations were influencing the settlements.

Mr. Beugler states that: "From the time-settlement curves for the various buildings it may be concluded that over-loading is responsible for most of the progressive settlement." This statement appears to be due to his belief that settlement "due to compression, shrinkage, and more or less elastic reaction, * * * ceases when the building is finished, or shortly thereafter, provided the unit loading of the soil has been selected conservatively."

It can be demonstrated easily in any soil mechanics laboratory that such belief is entirely without foundation, in so far as the compression of clay soils is concerned. The compression of a fully saturated, confined, clay sample never occurs instantaneously after application of the load, no matter how small the load increment is; and it can be extremely slow for very impermeable clays. Clays and silts from the northeastern, southern, and southwestern regions of the United States have been tested by the writer at Princeton University and have not shown any behavior, in this respect, different from the soils of Central Europe or Northern Africa. In all cases the permeability of a saturated clay exercised the most important influence on the rate of its compression. The relative influence of other factors may vary and will increase for more pervious or only partly saturated soils; but for fully saturated clays this influence always remained secondary as compared to the permeability of such clays.

An illustration of the contradictions in the aforementioned reasoning of Mr. Beugler is provided by Building IX (Fig. 11) which exerted a unit pressure of only 0.4 tons per sq ft on the surface of the ground. This pressure cannot be called anything but a conservative value for any soil, and it could not have been reduced further for the continuous mat of the building. The phenomenon of continued and gradually decreasing settlement of this building is fully explained by the gradual expulsion of water from the compressed voids of the silt and clay beneath the building, whereas "overloading" certainly does not offer any explanation. The settlements of this case almost ceased a year after the end of the construction, as should be expected because of the relatively thin compressible layer (20 ft). With a thicker layer they might have lasted much longer.

Soil Exploration for Foundation Work and Soil Testing Procedure for Engineering Classification Purposes.—Mr. Dames questions the value of the plastic and liquid limit tests when they are related to foundation soils in the undisturbed state, but overlooks the fact that nowhere in the paper were the plastic and liquid limits reported alone. In all cases a curve for each of these limits was plotted along the entire depth of the boring, side by side with a curve for the natural water content (in the undisturbed state). The curves for the compressive strength and the strains at failure, both in the undisturbed and in the remolded state, were plotted also. Any one of these tests is inadequate, if taken by itself; but it supplements the others so that, taken together, they give a good idea of the undisturbed nature of the soil profile.

The writer has a strong distrust of the sufficiency of descriptions of "appearance, texture, and local behavior," as suggested by Mr. Dames, unless they are accompanied by reliable data fixing the definite soil properties numerically. Such terms as "hard" and "soft" or "plastic" and "semi-plastic" may mean entirely different things to different people.

Shear and consolidation tests are undoubtedly among the most important, but they require so much time that in most cases it is not possible to perform them as routine classification and exploration tests. They then must be performed on a few selected samples only, as was done in Egypt. It should be mentioned here that, tested after complete disturbance, followed by full consolidation, at a rate of application of the shearing force equal to one-twentieth of the normal load per minute, both the dark and the brown clay had approximately the same value of the angle of internal friction (20 degrees). Only the cohesion varied.

The unconfined compressive-strength test on undisturbed samples extracted from borings was chosen as a routine test because it gives a direct measure of the cohesion of the soil and therefore of its shearing strength in the undisturbed state; at the same time, it can be performed much more rapidly than a properly conducted shear test. The strain at failure was given because it showed whether the undisturbed material was plastic (20% strain being taken as failure by plastic flow), semi-plastic, or brittle. The natural water content, given together with the plastic and the liquid limit, also illustrates the state of plasticity of the undisturbed soil.

In itself, an indication of the compressive strength in the undisturbed state is insufficient to identify a soil unless supplemented by an indication of the clay content or of the liquid limit. If the compressive strength has a low value, the liquid limit serves to show whether this is due to a low clay and silt content and to the resulting low cohesion (low liquid limit and low natural water content) or to an unconsolidated state of the undisturbed clay material (high liquid limit and high natural water content).

Some modifications of this method of soil exploration may naturally become desirable when dealing with other soil conditions. For instance, for soils that are permanently above the ground-water table, the indication of the volume, in place, may become desirable in addition to the water content. For sands and sandy silts, all laboratory tests could be replaced, usefully, by indications of the number of standard blows per foot required to force down a standard sampling spoon.

The method which the writer developed for work in Egypt is particularly adapted to conditions similar to the ones encountered there—that is, for the exploration of foundation conditions on cohesive soils beneath subsoil water level. Its practical advantages for such soil conditions appear to be recognized in the United States, since a similar method was used for the classification of soils along the Chicago subway.[25]

Limitations in the Value of Field Load Test.—Mr. Dames considers that the data given by the writer is not sufficient to "close the case" and to condemn load tests. No indiscriminate condemnation of such tests was contained in the paper; but, in suggesting load tests "not necessarily at foundation depth," Mr. Dames overlooks the fact that load tests are more unreliable than ever at elevations below subsoil water level. The excavation of a sheeted test pit to reach the layers likely to provide the "seat of settlement" (for instance, the dark clay) would have been entirely impracticable for the cases reported. It may be seen from Figs. 2, 4, 6, and 10 that the natural water content of the dark clay approaches very closely, and sometimes even exceeds, the water content at the liquid limit. When a boring was stopped for the night in a layer of dark clay or silt, one would very often find, in the morning, that it had been squeezed 2 or 3 ft up inside of the 6-in. steel casing of the bore hole. This would happen despite the fact that the casing had been kept filled with water to the very top in order to more than counterbalance any possible hydrostatic uplift pressure on the soil at the bottom of the bore-hole casing. The squeezing, therefore, was caused only by the weight of the overlying soil layers and of buildings in the vicinity. Short of using pneumatic caissons, in most cases there would be no way to make a load test on the dark clay in its really undisturbed state. Because of their high cost, pneumatic caissons have been used in Egypt only for some of the largest bridges.

[25] "Soil Tests Check Chicago Subway Work," by Ralph B. Peck, Jun. Am. Soc. C. E., *Engineering News-Record*, December 7, 1939, Fig. 1.

Mr. Dames advocates tests on footings of different sizes. Several semi-empirical theories have been developed for the purpose of estimating the settlement of a full-sized structure from data supplied by several test footings of different sizes. However, such estimates may be successful only when all the compressible layers can be reached by excavation and tested, and when each of these layers is homogeneous, horizontally, beneath the entire area occupied by the building. The numerous records from different localities examined by the writer tend to show that a naturally deposited soil layer with such a uniform degree of compressibility may be more in the nature of an exception than a rule and that non-uniform soil deposits near the surface are at least equally frequent.

Fig. 16 illustrates an extreme case in point and gives the results of load tests made on a weak surface layer, presumably an old fill, near Building *T*. Complete stabilization after each load increment was permitted, with at least 24 hr elapsing between the increments; the settlements were measured to about 1.0 mm (= 0.04-in.) accuracy, which is more than sufficient for all practical purposes. The writer wishes to emphasize that settlements cannot be measured in the open field to the accuracy of 0.001 in., as suggested by Mr. Dames. It is possible to provide dial gages reading to such accuracy, but thermal deformations of the necessarily long cantilevered supports, as well as other factors, preclude an actual accuracy exceeding 0.01 in. when observations are made over a period of several days.

It may be seen from Fig. 16 that the results would have been very embarrassing to any one who intended to use them for any estimates of the type suggested by Mr. Dames. The footing (10.8 sq ft) settled slightly more than the footing that was four times larger (43.2 sq ft). The reverse relation of the settlements should have been observed in homogeneous soil.

There was no opportunity for the advantageous use of soil load tests in any of the buildings described in the paper. Such tests can be applied only for testing surface layers above subsoil water level, thereby providing information that is seldom even of a limited practical value. In the few cases when it does have some practical value, the writer believes it preferable not to use footings of different sizes, but to make more numerous tests over the entire area of the future building with a small footing of some standard size—say, 1 sq ft. The results could then be compared, both individually and as averages, to a set of load-settlement curves for a footing of that same standard size, typical of the settlement of very hard and of very soft soils, and of intermediate types.

Effect of Excavation.—Mr. Beugler agrees with the writer that no decrease of settlement was observed as a result of excavation and states that this was doubtless true for the case cited (Building II). He then cites another case in which settlements were reduced by excavation after construction. This is quite understandable, since such excavation definitely reduces the pressures on compressible layers without allowing any dislocation of their structure. The writer has also reported a similar case.[26]

If the excavation is done before construction, however, everything will depend upon whether the deeper lying soil is dislocated as a result of the excavation. In the case of naturally stiff and impervious clays, any appreciable swelling may sometimes be prevented by draining the foundation pit properly and by rapid construction. The observations made under similar conditions at the Telephone Building at Albany, N. Y., led, at first, to unrestricted recommendations concerning the utility of excavation as the only reliable method for reducing settlements on clays.[27] Later observations disclosed limitations of the method in the case of weak plastic clays squeezed into the foundation pit. In extreme cases (Mexico, D. F., Mexico) the recorded rise of the bottom of the

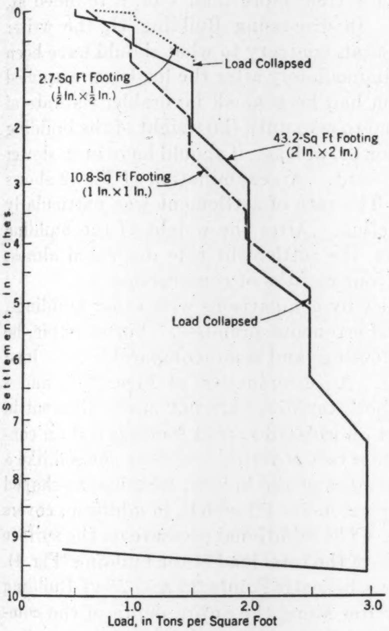

FIG. 16.—RESULTS OF LOAD TESTS ON WEAK LAYER OF IRREGULAR COMPRESSIBILITY

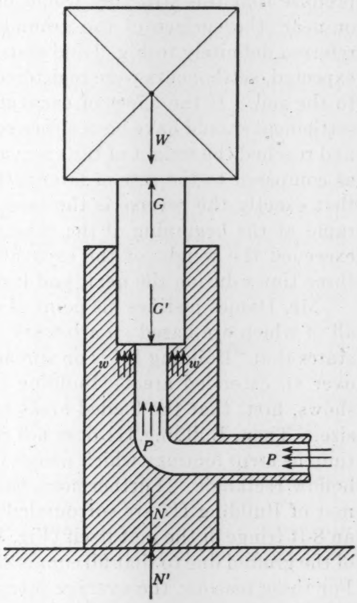

FIG. 17.—MECHANICAL EQUIVALENT OF INCORRECT ASSUMPTION CONCERNING THE SWELLING OF SOILS

pit sometimes reached 4 ft.[28] Special measures must then be adopted to counteract this rise and the accompanying weakening of the surrounding clay.[29]

[26] "Settlement Studies of Structures," by Gregory P. Tschebotareff, *Civil Engineering*, November, 1938, p. 751.

[27] "The Structure of Clay and Its Importance in Foundation Engineering," by A. Casagrande, Assoc. M. Am. Soc. C. E., *Journal*, Boston Soc. of Civ. Engrs., April, 1932, Fig. 28, pp. 191–193, and 203.

Observations on Building II have disclosed a further limitation when fairly stiff swelling clays and silts are permitted to absorb moisture after removal of the over-burden. No drainage could have helped here since excavation was extended to the lowest water level; furthermore, the foundation pit was left open for some time.

Mr. Dames states that "no data are introduced to disprove the logical premise that this structure would have settled more than 1 in. if founded at, or near, the surface of the ground." In discussing Building II, the writer referred definitely to Fig. 2 and stated that, contrary to what should have been expected, settlements were registered immediately after the loads were applied to the soil. If the effect of excavation had been at all favorable, the rate of settlement should have been either equal to zero until the weight of the building had reached the weight of the excavation or, at least, it should have been slower as compared to the rate of later settlement. An examination of Fig. 2 shows that exactly the reverse is the case. The rate of settlement was particularly rapid at the beginning of the construction. After the weight of the building exceeded the weight of the excavation, the settlement rate decreased almost three times during the next, and last, four months of construction.

Mr. Dames justifies his point of view by comparisons with other buildings, all of which are based on arbitrary and erroneous premises. For example, he states that "Building III is on spread footings and is not comparable as to load over an extended area" (Building II). An examination of Figs. 2, 3, and 4 shows, first, that the loaded areas of both buildings are not much different in size. Then, Building III does not rest on isolated spread footings but on continuous strip footings which merge into a raft covering a surface shaped like a hollow rectangle. Furthermore, three sides of the hollow, rectangular-shaped mat of Building III are surrounded by extensive fill which, in addition, covers an 8-ft fringe of the mat itself (Fig. 3). The additional pressure on the surface of the ground due to that fill equals 38% of the total load of the building (Fig. 4). For these reasons, the average pressures beneath Points 26 and 28 of Building III (Fig. 3(*a*)) as computed by the writer along the entire depth of the compressible layers above the sand are slightly greater than the corresponding pressures beneath Building II, even if these latter pressures are computed under the assumption that they have not been reduced by excavation. The type of soil formation is similar beneath both buildings. The thickness of the stressed compressible soil layers is slightly greater in the case of Building III (27 ft) than in the case of Building II (22 ft); nevertheless, over the same period of three years Building III has settled slightly less (20 mm) than Building II (22 mm). The comparison between these two buildings, therefore, is entirely possible and fully substantiates the statement of the writer that the excavation did not decrease the settlements of Building II.

[28] "Discussion of the Movements Within Foundation Pits During Construction," by J. A. Cuevas, Lazarus White, M. Am. Soc. C. E., and Karl Terzaghi, M. Am. Soc. C. E., *Proceedings*, International Conference on Soil Mechanics and Foundation Engineering, Vol. III, *Paper N-15*.

[29] "Modern Methods of Design and Construction of Foundations," by Lazarus White, *loc. cit.*, *Paper N-14*.

Buildings II and IV cannot be compared as suggested by Mr. Dames because his statement, "A similar sequence of soils both as to classification and description by the physical tests given exists under both of Sites II and IV," is incorrect. He overlooked the fact that beneath Building IV the dark clay was five times thicker than under Building II and later made an incorrect assumption concerning the compressibility of the dark clay.

Compressibility of Soils.—Mr. Dames assumed the dark clay of Building *T* to be just as compressible as the brown clay above it, whereas in all the cases reported in the paper the brown clay formed, on an average, a much more compact and stiffer material than the dark clay. This can be seen by examining Building IV in Fig. 6 where this difference was particularly pronounced. The brown clay had a natural water content of about 25% and a compressive strength varying from 1.3 to 3.2 tons per sq ft, whereas the deeper lying dark clay had a greater natural water content varying from 35% to 40% and a smaller compressive strength of about 0.7 ton per sq ft.

As stated in the paper, laterally confined, combined compressibility and permeability tests were also made on both types of clays and served to interpret the field observations. About forty such tests were actually performed. The "X" coefficients for these laboratory compressibility tests, performed in the usual standard manner, varied from 0.012 to 0.018 for different brown clays and from 0.024 to 0.045 for different dark clays.

Building I provided a key for an attempt to interpret and correlate the results of some of the field observations and laboratory tests. This was possible because the settlements of that building were caused almost entirely by the compression of a stiff brown clay layer (Fig. 1). The writer found the value of $X = 0.007$ to be approximately correct for the very stiff brown clay beneath Building I.[3] This value may be considered as not being too high for the still stiffer and more compact brown clay immediately beneath one of the wings of Building IV (Fig. 6). The compressibility of the compact brown silt beneath the rest of that building cannot exceed, to any extent, that of the brown clay. This follows from a comparison of the symmetrical computed lines of equal pressure and of the very slightly unsymmetrical lines of observed equal settlements (Fig. 5). The slightly greater settlement of the right wing of Building IV is directly proportional to the slightly greater depth of the compressible layers there.

Taking a value of $X = 0.007$ for the upper 18 ft of brown clay and silt, with an average pressure of 0.6 ton per sq ft along their depth, one obtains a value for their compression equal to: $0.007 \times 0.6 \times 18 \times 12 = 0.90$ in. Thus far, the total settlement has been reported as slightly exceeding 3 in. Thus, at least 2.1 in. of settlement must have been caused by the compression of the dark clay and silt. The dark silt is much less compressible than the dark clay, as demonstrated by tests, and a coefficient of $X = 0.007$ similar to that of the upper brown silt represents a liberal value for it. This gives a total compression of the 6-ft layer of dark silt equal to: $0.007 \times 0.5 \times 6 \times 12 = 0.25$ in. and leaves $2.10 - 0.25 = 1.85$ in. compression for the 10-ft dark clay layer. This figure, in turn, leads to the following average value of the compressibility coefficient for that dark clay: $X = \frac{1.85}{0.5 \times 10 \times 12} = 0.031$, which agrees well with laboratory test values for dark clays from different localities (ranging from 0.024 to 0.045). The clay is of the non-swelling type so that disturbances due to this cause cannot be considerable. Therefore, the value of $X = 0.030$ was reported as representing an average lower limit approximately determined from observations; the writer considers it to be reasonable. The approximations involved should not produce a cumulative error of much more than 50%; greater accuracies can never be reached for this type of work except accidentally.

The upper limit of $X = 0.070$ (a minimum average value) was reported for the dark clay on the basis of the field observations of Building IX only. The extremely high soil compressibility in this one case was very puzzling to the writer at first, until the examination of an old map made by the surveyors of Napoleon revealed that in 1798 the main channel of the Nile River flowed through what is now the site of Building IX. This gave a reasonable explanation for the abnormal compressibility since the river did not change its course until about 1850 when the present site was silted rapidly. The resulting soil formation, although covered by a relatively thin, dry, and hard crust, may be likened, therefore, to a hydraulic fill rapidly deposited over a horizontal surface of large area. Instances of the high compressibility of such fills have come to the notice of the writer.

The foregoing explanation appeared all the more reasonable since a further study of maps, based on medieval data,[30] showed that the sites of all other buildings were much more ancient and that the main channels of the Nile River near Cairo, Egypt, had not undergone any other appreciable changes since the Fourteenth Century.

Professor Hanna points out that in addition to swelling there must be also other sources of error, such as plastic deformations during sampling and friction along the sides of the testing ring. The writer has always fully endorsed similar views. Professor Hanna mentions some new studies he is undertaking and reports that "Preliminary results of these studies indicate that the author's statement that the method described in the paper has proved a success cannot be considered final." No such statement is contained in the paper; nor is it implied directly or indirectly. It would be entirely contrary to the views of the writer to suggest that any one method could take care of the numerous possible variables affecting the engineering properties in general, and the compressibility in particular, of different types of soils. The writer merely reported a method which disclosed the relatively great importance of the swelling of some compact clays as a source of error; this method also gave a procedure to counteract this swelling which checked with the field observations. Far from recommending the unrestricted use of this procedure, the writer presented a special discussion to the International Conference on Soil Mechanics and Foundation Engineering in 1936[31] for the purpose of stressing, on the basis of the observations of Building IV, the limitations when applied to non-swelling clays of the method described earlier.[3] In the present paper the writer has again stressed the limitations of this and other methods of settlement forecast and has emphasized the fact that they depended on the type of soil and on the method of sample extraction.

[30] "Cairo—Origin and Development," by C. R. Haswell, *Bulletin* de la Société Royale de Géographie d'Egypte, Tome XI, Decembre, 1922, Plate II.

[31] *Proceedings*, International Conference on Soil Mechanics and Foundation Engineering, Vol. III, *Discussion No. D-19.*

Pressure Distribution Computations.—Professor Krynine has stressed an important point by emphasizing the fact that the Boussinesq formula cannot be applied, very well, for estimating vertical pressures on deep lying compressible layers if these pressures are transmitted to the layers through an overlying, more rigid layer on which the foundation rests. In the writer's opinion, this "arching effect" of the upper layers, which relieves the pressures on the lower, weaker layers by distributing them over a greater area, should decrease in importance (1) with a decrease in the difference of the shearing rigidity of the two layers, (2) with a decrease in the thickness of the upper layer, and (3) with an increase of the area of the building. Therefore, in the case of the Egyptian buildings reported, this factor cannot have been very important. Any considerable excess in the assumed values of the actual pressures would mean that the assumed "X" values for the stiff brown clay ($X = 0.007$) would have to be increased and those of the dark clay ($X = 0.030$) decreased.

With reference to Fig. 15, the writer agrees that in some cases the average pressure in the ground may be neither at one-half nor at two-thirds of the depth of the compressible layer, but may have an intermediate value. However, for the ratio between the depth of the compressible layers and the foundation area of the cases reported, the foregoing assumptions do not involve an error exceeding 10%,[32] which is negligible as compared with the possible degree of accuracy of the settlement analyses as a whole.

Settlement of Pile Foundations.—Arbitrarily, Mr. Dames assumed that the compressibility of the dark clay is equal to that of the stiff brown clay ($X = 0.007$) and expressed the "belief that the settlement of Building *T* has been largely the result of individual pile failure and not due to the compression of the 10 ft of dark clay between the pile points and the sand."

Under the heading "Compressibility of Soils" herein the writer has explained that the foregoing assumption is entirely unjustified and that the estimated average compressibility of the dark clay under Building IV was $X = 0.030$. Earlier laboratory tests performed by the late Professor Kögler at Freiberg on soils from Building *T* had given approximate values of $X = 0.017$ for the brown clay and $X = 0.026$ for the dark clay.

Computations similar to the one performed for Building IV give the values of 5.3 in., 1.0 in., and 0.5 in. for the respective compressions of the dark clay, the brown clay, and the silty sand. Since the total observed settlement is 10.0 in., this leaves only 3.2 in. to be attributed either to too small values of X (taken at 0.026, 0.007, and 0.007 respectively) or to additional effects of plastic shearing deformations reaching to some distance around the piles. Such shearing deformations are likely to be relatively important only along the outside perimeter of the building. The term "group penetration" used by Mr.

---

[32] *Proceedings*, International Conference on Soil Mechanics and Foundation Engineering, *Paper No. E-1*, Fig. 18, pp. 57 and 58.

Dames is misleading since it implies the formation of a definite, vertical, shearing surface of failure in the soil around the pile groups and their "slipping" past the surrounding ground, together with the footings which cap them. No evidence of any such "slipping" could be obtained in this building. The very argument, correctly used by Mr. Dames to explain larger "group penetration" as compared to smaller single pile penetration, testifies against this conclusion in this case. The pile groups are so close to each other in the eastern part of the building that the shearing resistance between the stiff brown clay prisms confined by these groups and the piles themselves should be of the same order of dimension as the resistance to compression of the weaker dark clay supporting these prisms. Thus the piles supporting the building, on the whole, must have settled with the surrounding soil, except possibly along the outside perimeter of the building; and most of the surface settlement must have been caused by the compression of the lower lying dark clay layers.

To study this question further, in 1931 the writer introduced into the soil beneath Building *T* nine underground bench-marks almost identical to a type designed by Professor Terzaghi.[33, 34] They were placed in three groups at three different elevations. The results were satisfactory in a qualitative sense, showing that a large part of the settlement was due to the compression of the layers beneath the pile bearings, perhaps even including, to a slight extent, the deeper sand layers which have been assumed incompressible in this paper. However, the results from the separate bench-marks were unsatisfactory in a quantitative sense, since they were not in a logical numerical agreement with each other. It is impossible to say whether these numerical discrepancies were due to the fact that some of these bench-marks may have sunk slightly deeper into the ground under their own weight, thus registering too great settlements of deeper lying layers, or because other bench-marks may have been slightly pushed up as a result of swelling of the clay immediately adjoining them.

Under different conditions such bench-marks may give more consistent results. It would appear advisable to place them mainly in compact layers or relatively rigid soils, such as compact sands, and to place such underground bench-marks in several symmetrically located groups as could provide a check on each other through comparison with the performance of the foundation at the surface.

Effect of Ground-Water Variations.—Professor Hanna attempts to show that the buoyant effect of rising subsoil water is so small that it cannot account for the observed corresponding slowing down of settlements as suggested by the writer. The premises on which Professor Hanna bases this attempt are incorrect. Thus he states that when the period of construction coincides with the flood period, the corresponding increase of pressures due to the continued construction of the buildings ranges from 0.4 to 0.8 kg per sq cm. Only Buildings IV and V show any definite change in the rate of settlement during flood. An examination of Figs. 6 and 7 illustrating these buildings confirms the writer's previous statements and shows that in the three months during which the water rises the increase in their surface unit pressure was only 0.2 kg per sq cm or a

[33] "Die Tragfaehigkeit von Pfahlgruendungen," by Karl Terzaghi, *Die Bautechnik*, 1930, No. 34.

[34] "Settlement of Structures in Europe and Methods of Observations," by Karl Terzaghi, *Transactions*, Am. Soc. C. E., Vol. 103 (1938), Fig. 52(*a*), p. 1446.

value two to four times smaller than the one given by Professor Hanna. The corresponding increase in the pressures on the dark clay is only about 0.160 kg per sq cm. Thus, the value of 0.114 kg per sq cm, representing the maximum reduction of pressures on the dark clay due to buoyancy as computed by Professor Hanna, cumulatively counteracts 70% of the corresponding increase in the pressure of the building up to the moment when the peak of the subsoil-water rise is reached. This is more than sufficient to explain the observed discontinuities in the time-settlement curves of the two buildings, as has been done by the writer. Furthermore, the foregoing value of 0.114 kg per sq cm, which expresses the effect of buoyancy, is far from being excessive, as suggested by Professor Hanna, especially for Building IV. The subsoil-water rise at Building IV is much larger than the 2 m assumed by him (Fig. 5); and the coefficient 0.057 which he used (and which corresponds to 1 m water rise, of 35-lb-per-cu-ft buoyancy) is not too small since it does not take into account the capillary and entrapped moisture contained in the clay before the water rose. This should have been done for Building IV (see Fig. 5).

Professor Hanna further states that during laboratory compressibility tests which he performed "The pressures required to return a 12-mm sample to normal, when swelling occurs under the weight of the piston alone, vary between 0.18 and 0.30 kg per sq cm." The writer observed similar values during his own tests; but then Professor Hanna proceeds to attribute to these swelling pressures the observed changes in the rate of settlement of buildings and states: "Therefore, it is safe to assume that * * * the swelling of these layers reduces the pressure on the layer above them and, probably, to a slight degree, on the lower layers." The foregoing, he states, "is a mere assumption," and, the writer adds, an unwarrantable one. The pressure on the layer either immediately above or below the swelling layer will always remain equal to the superimposed weights and loads. The assumption made by Professor Hanna is equivalent to saying that an attempt to raise a load by a jack appreciably reduces both the weight of the load itself and the pressure of the jack on its support! That is (Fig. 17), if $p > 0$, then $G < W$ and $N' < N$. Obviously, this is impossible. If $p > 0$, then both $G = W$ and $N' = N$. Only "w" would decrease correspondingly—that is, the stresses in the swelling layer. This would reduce the component of the settlements due to the compression of the swelling layer itself; but, as discussed under the heading "Compressibility of Soils" herein, this settlement component is relatively small.

Conclusive evidence that the changes in the rate of settlement could not be primarily affected by swelling is provided by Building IV. Only part of that building rests on a strongly swelling brown clay, the remainder being supported by a silt which scarcely swells at all. Nevertheless, both the part supported by the brown silt (Point 16) and the part supported by the brown clay (Point 1) have shown exactly the same changes in the rate of settlement during changes in the subsoil-water level (Figs. 5 and 6). They should have shown a marked difference if Professor Hanna's assumption concerning the primary importance of swelling were correct for the cases reported in the paper.

On the other hand, the writer agrees fully with the explanation of the fact that the cracking of ancient houses in Cairo is particularly pronounced during the yearly flood. Not only do most cases of collapses of such houses occur during the seasonal flood, but during the same period many breaks occur in the water mains of Cairo. This must be due to the light weight of such old houses and water mains and to their incapacity to resist stresses induced by unequal swelling of the soil on which they rest.

Remolding of Clays.—Professor Hanna mentions some interesting and promising recent studies he made near the sea-coast on both brown and dark clays deposited in salt water which were very unfavorably affected by remolding, whereas similar fresh-water clays were not. It is difficult to decide at present whether the obvious conclusion from these studies could be generalized, since many glacial clays, presumably deposited in fresh water, are nevertheless found to be very unfavorably affected by remolding.

Conclusions.—The studies reported in the paper have provided much data of practical importance for local foundation designs. They have further served to prove the qualitative correctness of the general theories developed by the modern science of soil mechanics, which provide a surer basis for the exercise of sound engineering judgment. At the same time they have shown the quantitative limitations attached to numerical forecasts of the behavior of undisturbed soils.

Although much of the data given in the closing discussion has served to show the errors in some of the assumptions made by the discussers, the writer is glad that these assumptions were advanced, because he believes that the exchange of views has served to emphasize the complexity of the problems connected with settlement analyses and the necessity of having numerous co-ordinated observations on different structures before conclusions may be reached even for one locality.

The writer's work in this field constantly strengthens his conviction that further progress in the knowledge concerning the actual behavior, under stress, of undisturbed soils, is not possible on the basis of fragmentary data from isolated observations. The time involved in making systematic observations, as well as other reasons, precludes the possibility of their satisfactory execution by any single person or group of individuals unless this work is assigned to them as a regular, full-time job. This consideration, as well as the large investments depending on the satisfactory and economic design of foundations, coupled with the large degree of guesswork on which present codes and design methods are based, should justify the creation of special offices in most large cities for the purpose of making control observations, of the type described, on new structures.

POLLUTION OF BOSTON HARBOR

By Arthur D. Weston[1] and Gail P. Edwards,[2]
Members, Am. Soc. C. E.

With Discussion by Messrs. E. Sherman Chase, F. E. DeMartini, A. M. Rawn, Harrison P. Eddy, Jr., and Samuel A. Greeley, George A. Soper, and Arthur D. Weston and Gail P. Edwards.

Synopsis

The sewerage systems serving Metropolitan Boston are among the oldest in the United States, and the disposal works used in connection with these systems represent methods which require modifications to meet public demand for improved conditions. The discharge of sewage into Boston Harbor from these three systems has never resulted in depletion of oxygen in the tidal waters sufficient to cause a nuisance from odors but there have been increasing esthetic demands from the population residing in the vicinity of Boston Harbor for improved conditions because of sleek areas and pollution of beaches by floating matter. These increasing demands for improvements have been made regardless of the fact that the quantity of sewage discharged has not greatly increased in recent years.

The paper is framed chiefly around the results of a legislative investigation made in the years 1935 and 1936 under the general direction of the authors. It includes descriptions of the existing works and conditions of sewage disposal in harbor waters, presents results of chemical analyses and bacterial examinations sufficient in detail to permit comparison with data relative to the disposal of sewage in other tidal waters, discusses experimental work undertaken, and presents conclusions as to existing conditions and the best methods of meeting the demands for improvement.

Introduction

Under the provisions of Chapter 42 of the Resolves of the Massachusetts Legislature of 1935, a special commission[3] was appointed to investigate the

discharge of sewage into Boston Harbor and to consider what change, if any, might be necessary in any of the present systems of sewerage or sewage disposal in the territory tributary to the harbor in order to prevent nuisances or to remove objectionable conditions. The investigation was conducted during 1935 and 1936.

Boston Harbor is usually defined as that body of water inside or west of a line drawn from Deer Island to Pemberton in the town of Hull and extending to the lowest bridge on each of the tributary rivers and estuaries. It consists of four bays, Dorchester, Winthrop, Quincy, and Hingham, and an inner and outer harbor. The Mystic, Charles, and Chelsea rivers and Fort Point and Reserve channels are estuaries of the inner harbor. The total area of Boston Harbor is about 27 700 acres or 43.3 sq miles at high water. The volumes of the tidal prism of the average tide which enters and leaves Boston Harbor is 76 086 million gal. The quantity of water remaining at mean low tide is 108 305 million gal, and the total quantity of water at mean high tide is 184 391 million gal.

Drainage Area of Boston Harbor.—The tributary water-shed to Boston Harbor is about 645 sq miles. Included in this area, in whole or in part, are 53 cities and towns having a total population, according to the State Census of 1935, of 1 957 311.

Metropolitan Boston is served by three main sewerage systems (see Fig. 1), the Boston Main Drainage System, the North Metropolitan System and the South Metropolitan System. Included in this area are 32 towns and cities having a total population of 1 872 400 (or 95% of the population of the drainage area of Boston Harbor). The population contributing sewage in 1936 was estimated at 1 800 000.

The Boston Main Drainage System.—The Boston Main Drainage System was constructed during the period from 1877 to 1884 to intercept the sewage discharged at that time along the water-front from some 70 sewer outlets. It was designed to provide ultimately for sewage from 20 sq miles. The system was extended in 1892 and 1897 to intercept sewage from Waltham, Newton, Watertown, Brookline, the Brighton and Hyde Park section of Boston, Dedham, and Milton. Upon completion of the high-level sewer of the South Metropolitan Sewerage District in 1904 the system served only an area of 18.7 sq miles, consisting of Boston proper, South Boston, parts of Back Bay, the Roxbury, Dorchester, and West Roxbury sections of Boston, and an area of Squantum and Milton.

The system was designed to care for sewage at an average rate of 75, and a maximum rate of 112.5, gal per capita per day from a population of 800 000. In addition, it was designed for about 0.25 in. of rainfall upon the 20 sq miles in 24 hr, which was assumed to be at the rate of 0.01 in. per hr. All computations were based on the sewers running about half full and for the mingled storm water and sewage, in excess of the capacity of the sewer, to discharge through the old sewers as overflows. The resident population served by the district probably does not exceed 493 000 persons, but the per capita daily rate of sewage flow during the six months from June to November, in the period 1932 to 1935, inclusive, was 154 gal per capita instead of 75 gal per capita as originally contemplated. Estimates of flow on the basis of permanent population may be misleading in a municipality such as Boston, which has a large transient population in manufacturing and mercantile establishments, offices, and schools. In 1927 the number of people entering and leaving the business sections each day was estimated to be 825 000.

The trunk sewer of this system has a maximum diameter of 10.5 ft and terminates at a pumping station at Calf Pasture or Old Harbor Point where, after passing through cage screens of iron bars set with an opening of 1 in., the sewage is lifted about 35 ft and is discharged through force mains into two deposit sewers, each 8 ft wide, 16 ft deep, and having a total length of 1 260 ft. The velocity in these deposit sewers is about 1 ft per sec, and at their lower end the sewage flows over a weir into a tunnel to Moon Island off Squantum. The tunnel (see Fig. 1) is 7 160 ft long and 7.5 ft in diameter and is located about 143 ft below mean low water. At Moon Island the sewage is stored in four large reservoirs having a total effective capacity of approximately 35 400 000 gal. As far as practicable, sewage is discharged from the storage tanks on the second and third hours of the outgoing tide, and it enters the harbor at mean low water. The outfall sewer provided for this purpose is divided into two parts and is 10 ft 10 in. high and 12 ft wide on the inside. It extends 600 ft from the tanks to the tide water where there is a depth at mean low water of approximately 5 ft.

FIG. 1.—SEWERAGE SYSTEMS IN METROPOLITAN BOSTON

Table 1 shows the quantity of sewage pumped at the Calf Pasture Pumping Station and represents the quantity discharged into Boston Harbor from the Boston Main Drainage System. It is interesting to note that, whereas the maximum daily pumpage throughout each year has varied from 141% to more than 200% of the average daily value, the average daily amount pumped during June to November, inclusive, has varied little from that pumped on the average throughout the entire year.

TABLE 1.—ESTIMATED QUANTITY OF SEWAGE PUMPED IN MILLION GALLONS PER DAY

OVERFLOW OF SEWAGE FROM BOSTON MAIN DRAINAGE SYSTEM

The Boston Main Drainage System was designed to take care of some surface run-off in addition to the sanitary sewage; but for a number of years it has been considerably surcharged during storms because of the much larger amount of surface drainage that actually enters the system. At present (1939), during certain storms large quantities of mingled storm water and sewage enter the Charles River Basin and cause objectionable conditions. The Special Commission recommended[3] that legislation be provided to compel separation of storm water from domestic sewage in the city of Boston and that funds be appropriated to permit the construction of adequate works for removing storm water from the sewers in this district. Because of the impracticability of separating storm water from domestic sewage in the business sections of Boston, the ultimate solution of the problem probably would be to provide relief sewers of large diameter to divert the overflow of mingled storm water and sewage to parts of Boston Harbor where the least objectionable conditions may result so that the waters of the Charles River Basin and at certain beaches may not be polluted.

QUALITY OF SEWAGE FROM BOSTON MAIN DRAINAGE DISTRICT

Chloride determinations indicate that about 23% of the volume of sewage pumped in recent years has consisted of salt water which entered the system through leaks, or through tide gates, or by other means.

Table 2(*a*) gives the results of the analyses of the samples collected during the 1935–1936 investigation[3] and during the investigations of 1913 and 1929.

The material removed from the bar cage screens at the Calf Pasture Pumping Station is deposited on an adjacent dump to be drained and then burned.

ADEQUACY OF THE BOSTON MAIN DRAINAGE SYSTEM

At times of heavy run-off the storm water entering the main trunk sewers of the Boston Main Drainage System exceeds the capacity of the tunnel from Calf Pasture to Moon Island and the capacity at which it is practicable to operate the pumps at the Calf Pasture Pumping Station. At such times, large quantities of mingled storm water and sewage must discharge through the overflows provided for the purpose. If the full capacity of this main drainage system were utilized by increasing the pumping, the system could be made to deliver about 244 million gal in 24 hr; but this quantity is about 56% in excess of the designed capacity of the tunnel from Calf Pasture to Moon Island. Moreover, if it were possible to pass this quantity of sewage through the tunnel to Moon Island it would be necessary to increase the tank storage considerably at Moon Island if the sewage is to be discharged only on the second and third hours of the outgoing tide. Under present conditions these tanks are not allowed to fill above Grade 20, to prevent crowding of the tunnel and overflow of sewage from the deposit sewers at Calf Pasture.

It was the original intention that the stored sewage would be discharged only on the second and third hours of the outgoing tide, but from June to November, inclusive, during the eight years 1928 to 1935, the maximum average daily quantity of sewage pumped was about 84 million gal. Accordingly, it has been necessary, at times, to discharge the sewage on other than the second and third hours of the outgoing tide. The 1936 investigation showed that during the period from 1928 to 1936, inclusive, there have been 1 034 times when sewage was discharged either before or after the period in which the sewage was intended to be discharged, about 97 of which were made necessary by experimental work during the investigation.

POLLUTION OF BOSTON HARBOR BY THE NORTH METROPOLITAN SEWERAGE DISTRICT

The Metropolitan Sewerage District was created by acts of the Massachusetts Legislature in 1889 to provide sewerage facilities in the drainage areas of the Charles and Mystic rivers as recommended by the State Board of Health in the same year. The proposed Metropolitan District was to be divided into two parts, one part for the district north of the Charles River to be known as the North Metropolitan Sewerage District, and the other to provide for the diversion of sewage from the Charles River Valley into the Boston Main Drainage System. The North Metropolitan Sewerage District was to include the Charlestown and East Boston sections of Boston and the cities of Cambridge, Somerville, Malden, Chelsea, Medford, Melrose, Everett and Woburn, and the towns of Stoneham, Winchester, Arlington, Belmont, and Winthrop. Additional legislation has been provided from time to time authorizing extensions of the North Metropolitan Sewerage District, and in 1935 the size of the system and district[4] was substantially as shown in Table 3.

* At present connected with Boston Main Drainage System.

† Separate. ‡ Separate and combined. § Including two connections with McLean Hospital, having an estimated population of 803. ‖ Estimated by Superintendent of the Institution on Deer Island.

¶ Parts of Dorchester, West Roxbury, Roxbury and Milton, which are situated within the South Metropolitan Sewerage District limits, are tributary to the Boston Main Drainage System.

** Including connection with the Boston State Hospital, having an estimated population of 2 873.

†† Including connections with the Metropolitan State Hospital and the Middlesex County Tuberculosis Hospital, authorized by Chapter 372 of the Acts of 1928 and Chapter 373 of the Acts of 1929, having an estimated population of 2 078.

The North Metropolitan Sewerage System was designed to exclude storm water except in the cities of Cambridge and Somerville; and, to provide for an ultimate population of 571 000 in 1930, and for a flow of 210 cu ft per sec, or about 136 million gal per day. It was assumed that the volume of sewage to be cared for would be 30 cu ft per person in 24 hr except in the cities of Cambridge and Somerville where the sewers are on the combined plan and where an allowance of 35 cu ft per person per 24 hr was made.

There are approximately 74 miles of Metropolitan sewers in the North Metropolitan Sewerage District which vary in diameter from 10 to 109 in. The main sewer terminates at a pumping station at Deer Island where the sewage is screened and, by means of low-lift pumps, raised to an elevation that will permit it to discharge into the harbor by gravity through a system of multiple outlets. The discharge of sewage through the original outlet at this site caused complaints from the keeper of the Deer Island Light, and in 1917 the multiple outlets were provided. The present outfall, at its lower end, consists of 9-ft lengths of cast-iron pipe varying in diameter from 84 in. to 48 in. This pipe is open at the end and the thirteen lengths of pipe near the end have openings on the top. It is through these thirteen openings and the one at the end that sewage is discharged. The thirteen openings are practically elliptical in cross-section and vary in size from 44 in. by 25 in. to 23 in. by 13 in. The depth of water in the vicinity of these outlets is from 30 to 50 ft.

All the sewage from the district except Winthrop is pumped at a station at East Boston before reaching the Deer Island Station. The district also provides stations to pump the sewage from a section of Charlestown and from the Alewife Brook sewer which receives sewage from sections of Cambridge, Somerville, and Belmont; and a station is provided by the town of Winthrop to pump the sewage from that town into the North Metropolitan Sewerage System. Sewage at all of the Metropolitan pumping stations is screened through wrought-iron barred cage screens provided in duplicate.

QUANTITY OF SEWAGE FROM NORTH METROPOLITAN SEWERAGE DISTRICT

The estimate of sewage flow for the North Metropolitan District does not include the large quantities of mingled storm water and sewage entering Boston Harbor or its tributaries through storm overflows; and, accordingly, it cannot be considered alone in determining the adequacy of the North Metropolitan Sewerage System. Fig. 2 shows the estimates of flow of sewage from the North Metropolitan Sewerage District made by the Metropolitan District Commission. Table 1(*b*), for the period 1925 to 1935, includes maximum flow as a percentage of the average daily flow. The comparison of Table 1(*b*) with Table 1(*a*) shows that the flow during the maximum day is considerably greater from the North Metropolitan Sewerage District than from the Boston Main Drainage District.

ADEQUACY OF THE NORTH METROPOLITAN SEWERAGE SYSTEM

A comparison of the average daily flow for 1935 (82.9 mgd) with a flow of 136 mgd, which is the capacity for which the system was designed, would indicate that the capacity of this system in the maximum section is approximately 64% in excess of the average daily flow. The population served by this system in 1935 (696 470) was about 22% in excess of the 571 000 for which the system was designed. If storm water were excluded from the system except in the cities of Somerville and Cambridge, as originally proposed, many of the main trunk sewers in the lower part of the system would have adequate capacity to care for sanitary sewage. It should also be stated that, although the total population served by the system is only 22% in excess of that for which the system was designed, actually in some parts (namely, in the towns of Arlington and Belmont and Winchester) the 1935 population is from 3 to 12 times what it was when the system was designed.

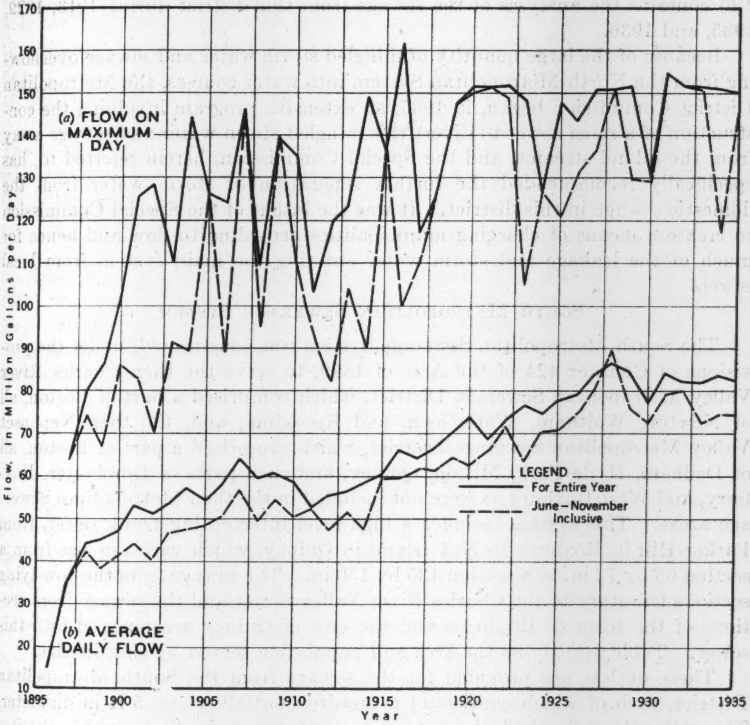

FIG. 2.—SEWAGE FLOW, NORTH METROPOLITAN SYSTEM

CHARACTER OF THE SEWAGE OF THE NORTH METROPOLITAN DISTRICT

Samples collected by the Massachusetts Department of Public Health during the investigations of 1929–1930 and 1935–1936 show that the sewage of the North Metropolitan Sewerage District is somewhat stronger than that of either the South Metropolitan or the Boston Main Drainage Districts. Approximately 19% of the sewage pumped at Deer Island consists of salt water which is believed to have entered the system through gates or leaks. Table 2(*b*) contains the analyses of the sewage from this district during 1913, 1929, 1935, and 1936.

Because of the large quantity of mingled storm water and sewage overflowing from the North Metropolitan System into water courses, the Metropolitan District Commission began, in 1935, an extensive program involving the construction of a relief sewer to divert this mingled storm water and sewage away from the inland streams, and the Special Commission, herein referred to, has specifically recommended the further separation of storm water from the domestic sewage in this district. It was the intent of the Special Commission to create a means of charging municipalities according to flow and hence for much of the leakage and storm water entering the main system from local sewers.

SOUTH METROPOLITAN SEWERAGE SYSTEM

The South Metropolitan Sewerage System was constructed, under the provisions of Chapter 424 of the Acts of 1899, to serve the then Charles River Valley Metropolitan Sewerage District, which comprised a part of Boston, all of Newton, Waltham, Watertown, and Brookline; and, the then Neponset Valley Metropolitan Sewerage District, which comprised a part of Boston, all of Dedham, Hyde Park, Milton, Quincy, and such parts of Dorchester, Roxbury, and West Roxbury as were not included in the then Metropolitan Sewerage areas. This system includes a high-level intercepting trunk sewer, from Parker Hill in Roxbury to Nut Island in Quincy, which varies in size from a section 68 by 72 in. to a section 135 by 150 in. The sewage from the low-lying sections tributary to the Charles River Valley Sewer and the sewage from sections of the town of Braintree and the city of Quincy are pumped into this sewer. Table 3(*b*) shows the area and population served by this district.

Three outlets are provided for the sewage from the South Metropolitan District, each of which consists of a cast-iron outfall sewer, 5 ft in diameter. The outlet through which the sewage is most commonly discharged is about a mile north of the screen house and about 1 200 ft from the westerly end of Peddocks Island. The second outlet, which is used at times in common with the first, is about the same distance from Nut Island and about 1 300 ft west of the first outlet, whereas the third outlet which is about 1 400 ft from the screen house has a point of discharge about 2 300 ft from the westerly shore of Peddocks Island. This latter outlet is used only in cases of emergency or at times of heavy run-off. At mean low tide the water over the two main outlets is about 30 ft deep and over the emergency outlet, 20 ft deep. These outlet pipes are laid in a trench at an average depth of about 9 ft below the bottom of the harbor. The outlets are encased in concrete and consist of a special casting in the form of a quadrant bend, 11 ft long weighing about 11 tons. Each pipe is surrounded by a rectangular timber casing 13 ft sq and 10 ft deep, resting upon 12 piles, 22 ft long. These structures are surmounted and surrounded by cut granite rings in six pieces, 30 in. deep.

The South Metropolitan Sewerage System was designed to serve an area of approximately 109 sq miles, but ultimately 218.19 sq miles will be tributary to this system. Except for the Charles River Valley Sewer (which receives the sewage from certain combined sewers), the South System is intended to receive only sanitary sewage. It was designed to take care of the sewage of a population of approximately one million persons on a basis of 300 gal per person per day in 1940. Records of the flow in this system, recorded at the screen house at Nut Island, show that the flow in 1935 averaged about 86.5 mgd.

Table 1(*c*) shows the flow in the South Metropolitan Sewerage System. The average daily flow of sewage from June to November, inclusive, was considerably less than that during the entire year, a condition contrary to that in the North Metropolitan Sewerage System and the Boston Drainage System.

Quality of Sewage Reaching Nut Island Screen House

Analyses of sewage collected by the Department of Public Health during 1913, 1929, and 1936 at the Nut Island screen house are as reported in Table 2(*c*). The chloride content of the sewage from the South District seldom exceeds 250 ppm indicating that only a small quantity of salt water leaks into the system of this district.

Effect of the Discharge of Sewage from Boston Main Drainage District and the North and South Metropolitan Sewerage Districts

For a number of years the discharge of sewage at Moon Island from the Boston Main Drainage District has caused objectionable conditions in the vicinity of the outfall because the discharged sewage enters the harbor at considerable velocity on the outgoing tide, at approximately the surface of the water, and spreads over a very large area, causing extensive sleek areas.

The sewage discharged from the North Metropolitan Sewerage District near Deer Island has never caused objectionable conditions except from odor in the vicinity of the Deer Island Light and from floating matter reaching nearby shores. Extensive sleek areas have seldom been noticed in connection with the discharge of sewage from this district. The limited size of the sleek areas is probably due to the rough water in that vicinity.

Although the sewage discharged from the South Metropolitan District does not result in as objectionable conditions as that from the Boston Main Drainage District, it does cause large sleek areas at times, especially in the vicinity of Nut Island on the incoming tide.

In order to ascertain the general condition of the harbor water resulting from the discharge of sewage from these three main outlets, an extensive program of sampling was conducted during the investigation by the Special Commission in 1935 and 1936 and, as far as practicable, these sampling stations conformed with those of previous investigations. Samples of the water were

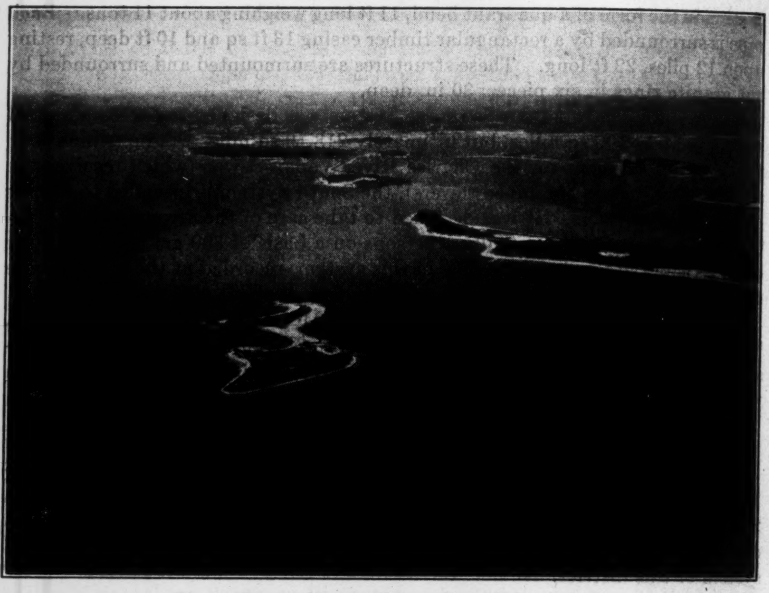

FIG. 3.—BOSTON HARBOR, FACING MOON HEAD OUTLET

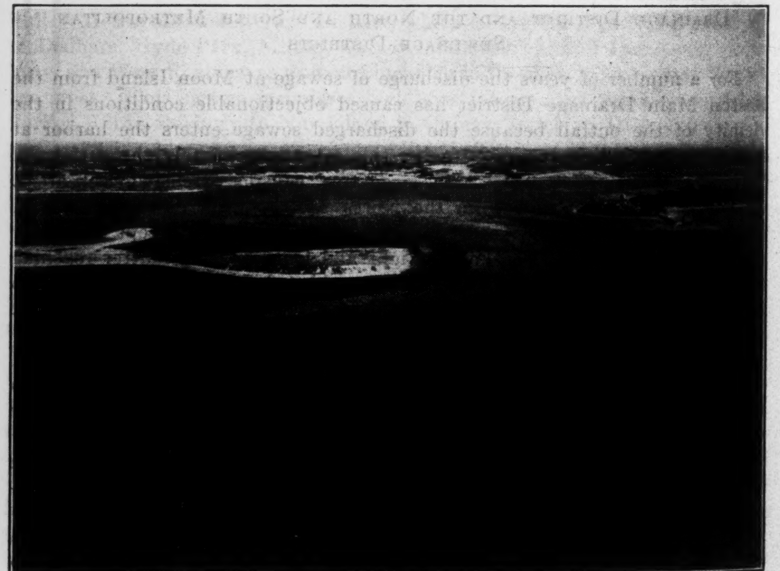

FIG. 4.—NUT ISLAND; 1.5 HOURS AFTER LOW WATER; NORTHWEST WIND; VELOCITY, 16 MILES PER HOUR

collected for chemical analysis and bacterial examination, and field tests were made to determine the quantity of dissolved oxygen in the water.

In order to interpret more intelligently the results of the chemical analyses and bacterial examinations, and in order to determine the extent to which sewage matters reach the shores of Boston Harbor and vicinity, extensive float tests were made to compare with the result of previous tests. To determine the extent to which floating matter, especially grease, might travel from these outlets, observations were made of sleek areas from boats, and a number of aerial photographs were taken (see Figs. 3 and 4).

Surface and depth samples were collected along the courses of floats for chemical analysis and bacterial examination; and samples were collected at regular intervals along the shores, especially in the vicinity of bathing beaches.

Tidal Currents in the Vicinity of the Outfall Sewers

The velocity and direction of the tidal currents were determined by observing the courses taken by floats released at the various outfalls and at other points throughout the harbor. Floats were also used to determine locations better adapted for points of discharge of the sewage. Three types of floats were used for this work—floats of deep submergence, surface floats of shallow submergence, and chips. The depth floats were constructed of 2 in. by 4 in. spruce timbers, 6 ft long, weighted at the bottom to hold the float in a vertical position and to provide submergence, except for 2 in. which extended above the surface of the water, and which was surmounted with a small signal flag. Each of the floats was equipped with vanes nailed to the sides to prevent whirling. The surface floats were similarly constructed of timber but were only 3 ft to 4 ft long. The chips consisted of small pieces of lath appropriately painted and marked by branding iron with the name and address of the Department of Public Health with the request that they be returned to the Department.

In general, the float tests confirmed the results of previous tests and showed that: (a) The velocity of the tidal flow in Boston Harbor has not changed considerably over a number of years, regardless of certain changes in and about the harbor due to the dredging operations and the filling of large areas for the construction of the Boston Airport, a bulkhead to Castle Island, and the filling in of Shirley Gut; (b) regardless of where sewage is discharged in Boston Harbor it may be expected that floating matter in the sewage will be washed on to the shores in the harbor or on adjacent shores. The courses taken by some of the floats released in various parts of the harbor are shown in Fig. 5, and Figs. 6 and 7 indicate the places where some of the chips were retrieved.

Results of Chemical Analyses

During the investigations of 1929 and 1930 the Department of Public Health made numerous tests on both the incoming and outgoing tides to determine the dissolved oxygen content in various parts of Boston Harbor, and during the joint investigation of 1935–1936 analyses and tests were made on samples from these same stations and at many additional ones.[3] The dissolved oxygen present in the water during the later investigation was found to

be in excess of that found in 1929 at all stations, and on the incoming tide it was in excess of that found during the 1930 investigation. At no time during the 1935–1936 investigation was the harbor water found to be less than 50% saturated, even in the vicinity of the main sewer outlets, and in the Inner Harbor opposite Fort Point Channel the dissolved oxygen content of the water averaged about 75% saturated. Except for the Inner Harbor the lowest

average dissolved oxygen saturation was 78.3%, which was found at a point a short distance northwest of the pier on Long Island. Determinations also were made[3] of the bio-chemical oxygen demand at various sampling points in the harbor (see Table 4). On the incoming tide in 1935 the oxygen demand was low in all sections of the harbor, the highest being 1.3 ppm in the Outer Harbor and Quincy Bay and the lowest being 0.3 ppm in Dorchester Bay. On the outgoing tide in 1936, the oxygen demand was somewhat higher, with a maximum of 4.1 ppm in Dorchester Bay. At no station where samples were collected did the results show that the dissolved oxygen in the water had been depleted sufficiently to cause a nuisance.

Although tests for B.O.D. have been made by the Department of Public Health of Massachusetts only during recent years, analyses for free and albuminoid ammonia have been made for many years, in some instances dating back to the early nineties in connection with pollution of tidal waters. Accordingly, it has been the practice of the Department to continue these analyses in order that comparisons may be made between these results and the old results where practicable. They show that, in most cases, the organic matter in the harbor waters during the 1935–1936 investigation[3] was about the same as in the 1929–1930 investigation. A slightly greater degree of contamination was found in 1936 at the entrance of Hingham Bay near Windmill Point, at the entrance of the Harbor north of Point Allerton, in the North Channel northeast of Deer Island, and in Winthrop Bay near Shirley Gut. The condition of the water in the Inner Harbor, in the vicinity of Boston proper, was somewhat better in 1935–1936—especially on the outgoing tide—than in 1929–1930. On the incoming tide in 1935 and 1936, the content of organic matter was greater, in Dorchester Bay, than in 1929 and 1930; and, on the outgoing tide, it was less. Because of the large concentration of dissolved oxygen in the harbor waters, the ammonia results were of greater assistance in determining the extent of pollution throughout the harbor than were the results of the tests of dissolved oxygen. In Fig. 8 the 1935–1936 results are shown in diagrammatic form as a means of comparison with the dissolved oxygen determinations.

BACTERIAL EXAMINATIONS

Earlier investigations as well as those of 1935–1936[5] show that the chief nuisances resulting from the disposal of sewage in Boston Harbor are those created by bacterial pollution and by floating matter from the sewage reaching the shores, especially the shores used for bathing.

The 1935 bacterial examinations showed that on the incoming tide the water at the surface of the Outer Harbor in the vicinity of Deer Island and Nut Island outlets contained large numbers of bacteria characteristic of sewage, and that the contaminated areas extended from the harbor entrance to the westerly part of Hingham Bay and into the easterly section of Winthrop Bay in the vicinity of Deer Island and Point Shirley. They also showed the presence of a large number of such bacteria in that section of the Charles River between the Inner Harbor and the Charles River Dam and, on the incoming tide, in the waters of the Outer Harbor entrances in the vicinity of Lovell, Gallups, and Georges islands; and, in a small area east of Deer Island. The samples collected on the outgoing tide contained large numbers of bacteria characteristic of sewage between the Inner Harbor and the Charles River Dam, in Fort Point Channel and along the Boston water-front. The waters of Dorchester Bay, in the vicinity of the Naval Air Base at Squantum, and in the vicinity of Commercial Point, contained large numbers of bacteria characteristic of pollution, a condition probably due to local contamination. Quincy Bay in the vicinity of Moon Island contained large numbers of bacteria on the outgoing tide, a condition due to the discharge of sewage from the outfall works of the Boston Main Drainage system. In the vicinity of Deer Island, water on the outgoing tide contained large numbers of bacteria in the northeasterly section of the Outer Harbor and at the entrances to the harbor. The results of samples collected in 1935 and 1936 show that on the outgoing and incoming tides the water, at a 20-ft depth in the vicinity of the outlets, contained a larger number of bacteria than at the surface; but at points close to the shore the number present was about the same in the surface and depth samples. On the incoming tide large areas of the Outer Harbor, Winthrop Bay, and parts of the Inner Harbor are contaminated by the discharge of sewage from Deer Island, and the entrance to the harbor is polluted, in addition, by the discharge of sewage from the Moon Island outlet. The 1936 samples showed that, on the incoming tide, the waters in the vicinity of the Deer Island and Nut Island sewer outlets, and in the vicinity of Long and Rainsford islands, are grossly polluted. Pollution in the vicinity of Long and Rainsford islands may be caused partly by the discharge of sewage from Long Island and from the return of sewage which had previously been discharged from Moon Island on the outgoing tide. This area appeared to be highly polluted on both the outgoing and incoming tides. The depth samples collected on the incoming tide showed a polluted area off the northwesterly shore of Thompson Island and between Gallups and Long islands and that under certain conditions the sewage from the Nut Island outfall sewer approaches the shore along Houghs Neck in Quincy. In general, on the outgoing tides the polluted areas were greater in 1936 than in 1935; but this condition may be explained in part by the fact that samples from a number of new sampling points between Long and Rainsford islands, between Long and Gallups islands, and north of Thompson Island, collected during the 1936 investigation, were not collected during the 1935 investigation.

FIG. 9.—DETERMINATIONS OF MEMBERS OF THE *COLI-AEROGENES* GROUP FROM SURFACE SAMPLE

groups. For conveniences, the lines connecting zones of equal *Coli-Aerogenes* density have been termed "isocols."

BACTERIAL CONDITION OF THE HARBOR BOTTOM

In connection with the bacterial investigation of the waters of Boston Harbor, samples were collected of the mud and silt along the bottom of the harbor at the regular sampling stations. In practically all cases the samples of mud contained many more bacteria, characteristic of pollution, than the waters at the surface, indicating that bacteria are deposited in the mud with sewage solids and are not washed out to sea with the outgoing tide. These results verify previous ones obtained by the Department of Public Health in the examination of certain bathing beaches where it was found that, although the waters over the beaches may sometimes be free from organisms of the *Coli-Aerogenes* group, the silt on the bottom at these beaches may contain large numbers of these organisms.

RECREATIONAL AND OTHER USES OF BOSTON HARBOR

Boston Harbor is used extensively for recreation and, to a limited degree, for the taking of shellfish for food. Although the harbor waters were not found to be so grossly polluted that nuisance from odor resulted, it is important to consider the effect of this pollution on waters used for bathing and from which shellfish are taken for food. Certain consideration should be given to the use of these waters for yachting. During the investigation by the Special Commission in 1935–1936, it was found that there were 21 yacht clubs along the shores from Point Shirley in Winthrop to Windmill Point in Hull, having a total membership of approximately 3 200 persons, and some 1 370 pleasure boats. It is interesting to note that at 6 of these clubs sewage was discharged directly into the harbor.

The sanitary surveys of 1935–1936 also showed that there were 29 areas between Point Shirley in Winthrop and Windmill Point in Hull where bathing beaches had been established. Of this number only 12 were under the control of the Metropolitan District Commission or the City of Boston, and at many of the areas no bath-houses or close supervision were provided. It was estimated that approximately 100 000 persons frequent the popular beaches on some pleasant Sundays and that 15 000 additional persons use those beaches where no record of attendance is kept.

In order to compare the results of the bacterial examination of the samples of the water collected at the beaches of Boston Harbor and some of those outside the harbor, Table 6 is presented. It is apparent that the beaches in Boston Harbor are more highly polluted than those outside but not as grossly polluted as at some beaches on streams tributary to the harbor. Some of the areas in Boston Harbor, now used for bathing, must be abandoned for that purpose, or a considerable sum of money must be expended to treat the sewage, or to remove it by extending the present sewer outlets to points more remote from the beaches. The investigation failed to disclose any illness due to bathing in these waters; but, regardless of the lack of such evidence, it is obvious that there must be always a danger to public health where bathing is permitted in the vicinity of sewer outlets. Accordingly, the Special Commission stated in its report to the Legislature[6] that in view of the numerous clean beaches available to the public there was no good reason to permit bathing near sewer outlets, and that public bathing along the water-front of Boston Harbor and its estuaries and tributaries should be restricted to such areas as may meet with the approval of the Board of Health of the city or town in which such bathing site is situated, or with the approval of the State Department of Public Health.

TAKING OF SHELLFISH FROM BOSTON HARBOR

The taking of shellfish from Boston Harbor is regulated by acts of the Massachusetts Legislature. Also in accordance with Massachusetts laws, the Department of Public Health has permitted master diggers, under permits issued by the Supervisor of Marine Fisheries, to take shellfish from certain areas in Boston Harbor for treatment purposes at an approved shellfish purification plant. Fig. 10 shows the areas in Boston Harbor where shellfishing was permissible as of July 1, 1937, either for treatment purposes or for use as food without treatment.

FIG. 10.—SHELLFISH AREAS IN BOSTON HARBOR AS OF JULY 1, 1937

EXPERIMENTAL SEWAGE TREATMENT WORKS

The ordinary routine investigation to determine the most appropriate method of sewage treatment would consider the capacity of the water in which the effluent is to be discharged to replenish the oxygen that would be consumed by the bio-chemical processes of the purification of the sewage. There is no question of the capability of the tidal prism of Boston Harbor on the outgoing and incoming tide, and the waters of the streams tributary to this harbor, to supply sufficient oxygen to replenish that consumed by the disposal of sewage in the harbor.

Bacterial examinations, tests for dissolved oxygen, and chemical analyses, were made of the waters of Boston Harbor, and of sewage discharged from the North and South Metropolitan Sewerage districts and the Boston Main Drainage District. They indicated that objectionable conditions can be removed if works are provided for the removal of certain suspended matters and grease from the sewage before it is discharged. The settled sewage may be chlorinated should further reduction of bacteria of the *Coli-Aerogenes* group become necessary.

To determine the most practicable method of treating this sewage, experimental plants were constructed at Deer Island for use in connection with the sewage of the North Metropolitan Sewerage District, at Nut Island in connection with the sewage of the South Metropolitan District, and at Calf Pasture and Moon Island in connection with the sewage from the Boston Main Drainage District. The small-scale experimental plants consisted of fine screens, a 1 000-gal settling tank, and a 650-gal tank used for pre-aeration of the sewage to aid in the removal of grease. The settling tank was provided with suitable baffles for removing the floating solids. The detention period varied from 1 to 6 hr. In addition, experiments were made to determine the reduction of the number of bacteria of the *Coli-Aerogenes* group by discharging the sewage into salt water. The pump used had a rated capacity of 40 gal per min but under the conditions of operation did not exceed 30 gal per min.

The experimental apparatus used in connection with the South Metropolitan District was similar to that of the North, as was also the apparatus used in connection with the experiments on the sewage from the Boston Main Drainage District at Calf Pasture. Provisions were also made for large-scale experiments on Moon Island whereby one of the large storage tanks having a capacity of about 8 million gal was utilized.

EXPERIMENTS AT CALF PASTURE

The results of the experiments on plain sedimentation, including 1, 1.5, and 2 hr of detention on a continuous flow basis and 3, 4, 5, and 6 hr of detention on an intermittent basis are shown in Table 7(*a*).

As was expected the suspended solid removal in these experiments was about 30% in 1 hr and 50% in 2 hr. The additional removal after detention periods greater than 2 hr was small, being only a total of 62.5% in 6 hr. Removal of the organic matter as represented by the bio-chemical oxygen demand (about 19% with a 2-hr detention period) was relatively low. The removal of the nitrogenous matter as represented by the albuminoid ammonia and Kjeldahl nitrogen determinations was 21% and 21.9%, respectively, for a 2-hr detention period. In these experiments there was little relation between the grease removal and the detention period but the results indicate that about 40% of the grease can be removed by skimming during a plain sedimentation period of 2 hr.

The experiments made to determine the quantity of grease that could be skimmed from the surface of the tanks with aeration prior to sedimentation showed that a slightly greater proportion of grease could be removed with pre-aeration. The additional detention period resulting from aeration was about one-third of the total aeration period. Pre-aeration, however, resulted in a greater reduction in the percentage of suspended solids and nitrogenous matter. The percentage of removal of the suspended solids by plain sedimentation was about 50% for a 2-hr detention period, whereas with pre-aeration, the removal was about 57% for 2.25-hr periods. The results of the sedimentation tests, with pre-aeration, are shown in Table 7(*b*).

The sewage used in the experiments for the Boston Main Drainage System was obtained at the Calf Pasture Pumping Station from a chamber at the entrance to the deposit sewer. The experiments were made on the sewage from this district 24 hr per day for a 7-day week from September 26 to November 21, 1935.

EXPERIMENTS ON THE SEWAGE OF THE NORTH METROPOLITAN SYSTEM

The Deer Island experimental plant was operated for the most part 16 hr a day, from 7 A.M. to 11 P.M. Early in the morning the sewage was generally at such a low level that it was impracticable to raise it with the equipment used. The period of experimentation was from September 30 to November 9, 1935, and from May 15 to July 31, 1936.

In the plain settling tests the average reduction in suspended solids was about 45% in 1.5 hr, 51% in 2 hr, and 57% in 3 hr. The average B.O.D. reduction was about 25% during these periods and the reduction of nitrogenous matter, as represented by the Kjeldahl nitrogen determination, was 33 per cent. Approximately 40% of the grease in the sewage was removed in a detention period of 2 hr. Table 7(*d*) shows the results of the plain sedimentation experiments.

EXPERIMENTS ON SEWAGE OF THE SOUTH METROPOLITAN SEWERAGE DISTRICT

The experiments on the sewage from the South Metropolitan Sewerage District were extended over a period from 7 A.M. to 11 P.M. from Monday to Friday, inclusive, from August 25 to September 19 and October 2 to October 9, 1936. Because of the short period of operation a few of the samples were 4-hr composites instead of the usual 8-hr composites. The sewage for these experiments was taken from the main outfall sewer through a manhole to the grit-chamber at the entrance to the screen house at Nut Island. The efficiency of settling was much greater in connection with the sewage of the South Metropolitan System than from the Boston Main Drainage System although the analyses showed that the sewage of these two systems was similar. The reduction in suspended solids during a 2-hr detention period was 69% as compared with 50% ordinarily obtained. The reduction in the oxygen demand, organic nitrogen, and oxygen consumed, was 40%, 40%, and 36%, respectively. It is probable that if the experiments had been extended over a sufficient period, lower reductions, more consistent with the results of the experiments on the sewage of the Boston Main Drainage System, would have been obtained. Table 7(*e*) shows the results of plain sedimentation experiments on the sewage of the South Metropolitan Sewerage System.

Summary of the Results of Sedimentation Experiments

Pre-aeration of the sewage to aid in grease removal was not successful in connection with sewage of the Boston Main Drainage System and the North Metropolitan Sewerage System. It is probable that the aeration does help to separate the grease from the settleable solids; but it is doubtful if, in these experiments, it was of sufficient assistance in increasing the over-all removal of grease to warrant the additional expense.

These experiments, confirming the result of other similar experiments, show that the greatest reduction of suspended solids occurs during the first hour and that with increasing detention periods the increments of removal become less and less.

In general, the results obtained from all three stations were similar and indicated that about 50% of the suspended solids could be removed in a 2-hr detention period. Calculated from the removal of suspended solids, the daily quantities of sludge that would be removed from the sewage of the three sewerage systems on the basis of 1935 flows is shown in Table 8.

TABLE 8.—Quantity of Sludge Expected per Day

System	Dry solids, in tons	Sludge (95% moisture), in gallons	Sludge (80% moisture), in cubic feet
Boston Main Drainage	25	114 000	3 800
North Metropolitan Sewerage	33	153 000	5 120
South Metropolitan Sewerage	30	138 000	4 610
Totals	88	405 000	13 530

Experiments with Fine Screens

The solids obtained by passing the sewage through fine screens, 18 in. by 21 in., which had openings of $\frac{1}{16}$ in., $\frac{3}{32}$ in., and $\frac{1}{8}$ in., by 2 in., is shown in Table 9. The nature of the screenings is described as follows:

Experiment station	Screenings
Calf Pasture	Garbage and paper, with leaves after a heavy rain
Deer Island	Garbage and paper with some hair and bristle
Nut Island	Garbage and paper

Because the Boston Main Drainage System is relatively short, more screenings were obtained from sewage of this system than from that of the larger North and South Metropolitan Systems where the larger particles in the sewage have an opportunity to become well disintegrated before reaching the screen chambers.

The weather during the tests was about normal except during the day of September 18, 1936, when the $\frac{1}{16}$-in. screens were in use at Nut Island. At this time 4.64 in. of rain fell and screenings were obtained at the rate of 143 lb of dry material per million gallons of sewage.

Large particles of floating and suspended solids were removed with the use of fine screens. Only a small quantity of the grease (one of the main offenders in rendering the harbor waters unsightly) was retained on the screens, and it is apparent that fine screens without additional help are insufficient to improve the objectionable appearance of the harbor satisfactorily. Only about 5% to 8% of suspended solids were removed by the fine screens as compared with about 50% removal by plain sedimentation.

LARGE SCALE EXPERIMENTS, BOSTON MAIN DRAINAGE SYSTEM, 1936

Mention has been made herein of the use of one of the large storage tanks at Moon Island for continuous flow experiments to determine the removal of suspended solids and grease from the sewage of the Boston Main Drainage System. These experiments were conducted in the first place to compare, so far as practicable, the results of the small scale experiments with those of the large scale, and to give some indication of the possible use of the present equipment of the Boston Main Drainage System for purposes of sedimentation and grease removal. The tank used was trapezoidal in shape, 162 ft wide, and had an average length of 612 ft. The floor at the outer end, which is slightly lower than that of the inner end, was at Elevation 9 (mean sea level). The tank was equipped with a dike, with weir and skimming baffle and gates to prevent the sewage from flowing out of the bottom. The skimming baffle consisted of a floating, vertical, wooden structure about 3 ft deep, 2 ft of which were submerged, held 6 ft out in front and parallel to the sides of the dike by spreaders. The spreaders were connected in such a way as to allow the baffle to rise and fall with the level of the sewage. It was the purpose of the baffle to prevent the passage of this floating matter over the weir. During the first experiment, from August 11 to September 4, the settled sewage was stored in the three remaining tanks and discharged to sea in the regular manner on the second and third hours of the outgoing tide. Sewage from the experimental tank was discharged to sea for two hours longer to compensate for the loss of one tank from the total of the storage capacity. The average detention period in the tank was estimated to be about three hours. Beginning September 8, experiments were made in the same manner except that the sewage was discharged to sea continuously; that is, the three storage tanks were not used, sewage passing through the experimental tank only. This part of the experiment was discontinued on September 18. At the conclusion of each week's run on Friday evening, the sluice gates were opened to allow the basin to drain and the lower section of each bulkhead was removed and the basin flushed out. Frequent cleaning of the tank prevented the occurrence of septic conditions with the formation of gas which would interfere with sedimentation. The scum was discharged to sea on the outgoing tide, as necessary. Samples of the raw sewage and the settled sewage were collected each half-hour and composited over an 8-hr period. Determinations for dissolved oxygen and pH were made in the field and the regular chemical determinations were made in the laboratory. The experiments were run continuously from Monday morning through Friday evening. Because the weir was submerged much of the time, accurate weir measurements of the flow could not be made, but estimates were made from the level of sewage in the basins before discharge. Considerable sewage, perhaps 5 to 10 mgd, escaped through the stop planks in the boat chamber, or through the numerous gates, and were not treated in the settling tank.

During continuous discharge, the weir readings were made every two hours and these measurements should show rather accurately the quantity of sewage treated in the settling tank; but they did not necessarily show the total flow to Moon Island, because of the losses mentioned. The large scale settling and skimming tests at Moon Island were made over a period of 28 operating days. During these experiments, harbor and shore samples were collected in addition to the regular composites of raw and settled sewage. Samples of the scum and sludge were also collected to determine their value for grease recovery and for fertilizer or fill.

The detention period varied from 1.7 to 5.8 hr and averaged 2.8 hr. During the test the average daily flow through the tank was about 60 million gal. The average results of the settling tests for the entire period are shown in Table 10.

The raw sewage from the Boston Main Drainage System, during the tests of 1936, was somewhat weaker than during the experimental work in 1935 at Calf Pasture. The concentration of suspended solids was particularly less in 1936, averaging about 162 ppm in 1935 and 119 in 1936. The strength of the sewage varied from hour to hour and from day to day. The strongest sewage was received during the afternoon and early evening, and the weakest sewage arrived in the early morning. The suspended solids in the raw sewage varied during the tests from 50 to 302 ppm. It is interesting to note that the removal of the material by sedimentation, in the large tank experiments, compared favorably with those obtained in the small unit on the sewage from this district at the Calf Pasture Pumping Station.

In connection with these experiments, it should be remembered that the large basin used for the experiment was designed as a storage tank and not as a settling tank, and accordingly the distribution of the sewage at the inlet was poor. The length of the effluent weir was small for the large volume of sewage, and the velocity of approach to the weir was relatively great. When a large volume of scum accumulated in the tank, the velocity of the sewage carried some of the scum under the baffle and over the weir. Considering the fact that the large chamber was not well fitted for settling and skimming of sewage solids, the results obtained were very satisfactory and indicated that better results might be expected with a tank properly designed and operated.

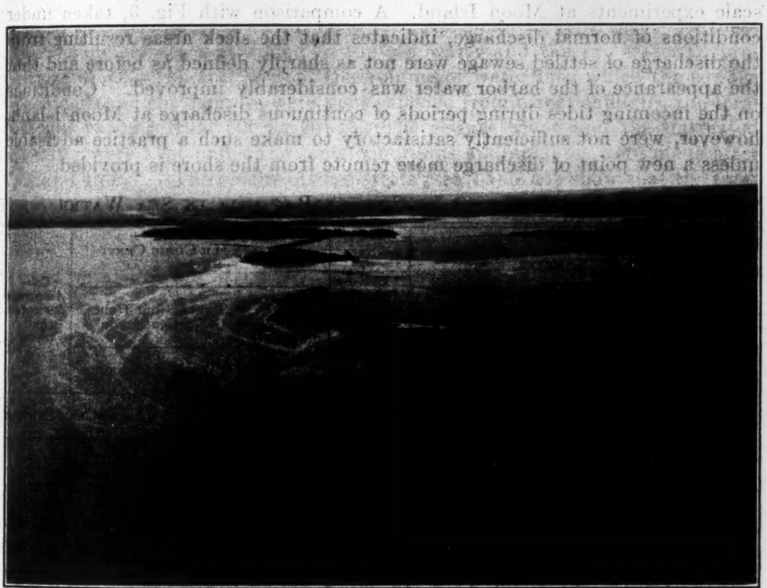

FIG. 11.—VIEW OF MOON ISLAND, SHOWING IMPROVEMENT OVER CONDITIONS IN FIG. 3

It was impracticable to measure the sludge removed as it was distributed over the bottom of the tank in a thin layer, and it was impossible to draw down the tank without disturbing and losing some of the solids. However, calculations made from the reduction of the suspended solids indicate that, in all probability, an average of 21.2 tons of dry solids were removed daily, which compares favorably with the estimates obtained during the Calf Pasture Pumping Station experiments.

The quantity of floating matter held back on the surface of the sewage by the skimmers was much greater than expected, and rough estimations indicate that as much as 40 cu ft per million gal of sewage may be removed in this manner. The grease content of the sewage varied considerably from day to day. The average results of the analyses of the scum showed that it contained about 89% moisture and 77.5% volatile matter. An average of 42% of the dry solids was fat and 2.8% was Kjeldahl nitrogen.

The raw sewage had an average of 34.2 ppm of fat which was reduced to 20.0 ppm by sedimentation, a reduction of 41.5 per cent.

In order to determine the effect on the harbor waters, of the discharge of settled sewage, aerial photographs such as Fig. 11 were taken during the large-scale experiments at Moon Island. A comparison with Fig. 3, taken under conditions of normal discharge, indicates that the sleek areas resulting from the discharge of settled sewage were not as sharply defined as before and that the appearance of the harbor water was considerably improved. Conditions on the incoming tides during periods of continuous discharge at Moon Island, however, were not sufficiently satisfactory to make such a practice advisable unless a new point of discharge more remote from the shore is provided.

VIABILITY OF SEWAGE ORGANISMS IN SALT WATER

Studies made by the Massachusetts Department of Public Health to determine the effect of polluted water on quahaugs, a mollusk of the hard-shell variety, showed that quahaugs obtained from polluted waters were comparatively free from organisms of the *Coli-Aerogenes* group after immersion for 48 hr in clean sea water. In order to ascertain if the disappearance of organisms of this group was due to the shellfish themselves or to the sea water, or both, experiments were conducted at the Lawrence Experiment Station of the Department of Public Health to determine the reduction of bacteria of the *Coli-Aerogenes* group in sewage when discharged into sea water. Similar experiments also were made to show the effect on these bacteria when discharged into the water drawn from a tap of the city of Lawrence. In these experiments, sewage was added to the sea water and the tap water in proportions of ½%, 1% and 1½% of the volume of water into which the sewage was added, and the samples were kept shielded from direct sunlight, the temperature varying from 50° to 70° F. The sewage alone and the untreated sea water were kept under the same conditions and analyses were made after 1, 2, and 4 days. The results of these tests (see Table 11) show that the total bacteria in the samples incubated at 20° and 37° C, as well as the organisms of the *Coli-Aerogenes* group, decreased very slowly in the sewage and the tap-water mixture, but very rapidly in the sewage and sea-water mixture. Because of this very considerable reduction in the numbers of bacteria in some instances, in the first 24 hr, the experiments were later continued by providing shorter periods of contact of the sewage with both the fresh and salt water. The latter results are shown on Fig. 12, a comparison between regular sewage and Nahant sea water being as follows:

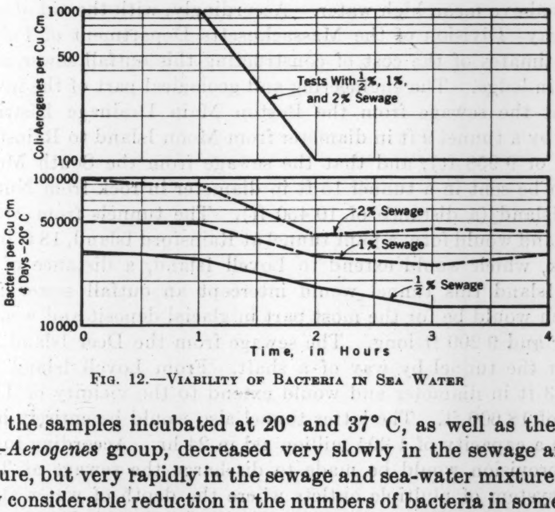

FIG. 12.—VIABILITY OF BACTERIA IN SEA WATER

Sample	Number of bacteria per cubic centimeter	Number of *Coli-Aerogenes* per cubic centimeter
Regular sewage............	5 300 000	100 000
Nahant sea water.........	770	1

REMEDIAL MEASURES CONSIDERED FOR ALLEVIATING POLLUTION OF BOSTON HARBOR

Although the discharge of sewage into Boston Harbor has not as yet caused conditions dangerous to the public health, objectionable floating matters characteristic of sewage may sometimes reach certain shores and, in the future, the demands of the public may require improvement.

To eliminate the pollution of Boston Harbor, either the sewage may be: (1) Discharged farther out to sea; (2) treated for the removal of suspended solids and grease before its discharge into the harbor; or, (3) treated to remove the solids and then conveyed by tunnel and discharged outside the harbor. Consideration was given to the construction of an outfall sewer which would intercept the sewage from the existing main sewer outlets—namely, the North Metropolitan outlet at Deer Island, the outlet of the Boston Main Drainage District at Moon Island, and that of the South Metropolitan outlet at Nut Island—and which would have a point of outfall in the Outer Harbor in the vicinity of The Graves. It was found to be impracticable to construct such an intercepting outfall sewer unless it was in the form of a tunnel, because Boston Harbor consists of a number of deep valleys filled with clay and other glacial deposits. Between these valleys are peaks of ledge which reach in some places above mean high water. Accordingly, with the aid of a geologist, the Waterways Division of the Massachusetts Department of Public Works prepared estimates of the cost of constructing this outfall sewer in the form of a tunnel in ledge. The engineering and geological part of the investigation showed that the sewage from the Boston Main Drainage District can be disposed of by a tunnel 9 ft in diameter from Moon Island to Rainsford Island (a distance of 9 950 ft); and that the sewage from the South Metropolitan District can be sent in a tunnel 15 ft in diameter in rock from Nut Island to Rainsford Island (a distance of 10 450 ft). The tunnels from Moon Island and Nut Island would form a joint tunnel at Rainsford Island, 18 ft in diameter, also in rock, which would extend to Lovell Island, a distance of 10 000 ft. At Lovell Island this tunnel would intercept an outfall sewer from Deer Island which would be for the most part in glacial deposit and would be 14 ft in diameter and 9 200 ft long. The sewage from the Deer Island connection would enter the tunnel by way of a shaft. From Lovell Island the tunnel would be 23 ft in diameter and would extend to the vicinity of The Graves, a distance of 18 600 ft. The latter tunnel also would be entirely in rock and would have a capacity of 1 205 million gal in 24 hr. According to the design proposed, provision would be made to discharge the sewage at The Graves through a system of multiple outlets where the depth of water at mean low tide is 30 to 35 ft. The estimated capitalized costs of these outlet works, including the radial outlets from the terminal chamber and all tunnel construction, but not including the cost of new pumping facilities, were $26 100 000. The capacity of these works which was for a flow of sewage amounting to 1 205 mgd is approximately five times the average daily flow of sewage from these districts in 1935.

Chips that were released in the vicinity of The Graves reached the shores of Boston Harbor and various points along the coast remote from The Graves, proving rather conclusively that, if the sewage is to be prevented from reaching the shores and causing objectionable conditions among bathers, it will be necessary, even with the outlet as remote as at The Graves, to treat it for the removal of grease and floating matter. Under the circumstances, the plan of extending the sewer outlets to the vicinity of The Graves would not appear to be justified until it is necessary to provide such works in connection with the disposal of treated sewage. Fig. 1 shows the location of the suggested outfall works to The Graves.

The most economical plan appeared to be to provide treatment works in the vicinity of the main sewer outlets at Deer Island, Moon Island, and Nut Island. When the treated sewage discharged from such works causes objectionable conditions in the harbor a program of progressive tunnel development can be provided which will permit the treated sewage to be discharged, in the beginning, in the vicinity of Rainsford Island. Float tests indicated that, near this island, sewage treated for the removal of grease and suspended wastes could be dissipated on either the incoming or outgoing tides before reaching any of the main ship channels.

Treatment works for the removal of suspended solids and grease would consist of bar screens and sedimentation tanks with skimming and sludge removal equipment. The skimming and sludge would be disposed of by barging to sea. The first cost of such works for the three districts, including the cost of operation and the cost of disposing of the sludge, grease, and other floating matter, together with the cost of additional pumping, is shown in Table 12.

TABLE 12.—FIRST COST OF TREATMENT WORKS

Description	Boston Main Drainage System	North Metropolitan Sewerage System	South Metropolitan Sewerage System
First cost of works consisting of bar screen with mechanical cleaning devices, sedimentation tanks with skimming and sludge removal equipment	$2 907 000	$ 5 539 850	$ 6 023 100
Capitalized cost of operation and disposal of skimmings, screenings, and sludge by barging to sea, to 1955*	3 300 000	7 190 000	7 560 000
Annual charges	(123 630)	(269 910)	(283 290)
Total cost of partial treatment to 1955	$6 207 000	$12 729 850	$13 583 000

* Interest at 3¾ per cent.

SLUDGE DISPOSAL

The problem of sludge disposal is usually the most difficult one to be solved in the treatment of sewage. The location of the proposed plants on islands in Boston Harbor points at once to the disposal of sewage sludge by barging to sea; and this would undoubtedly be the most economical method, especially if the sludge could be carried to sea as cheaply as is done by the Passaic Valley (N. J.) Sewerage District where the cost is only 14.7 cents per wet ton. In Boston, operation of sludge steamers or barges by the authorities in charge of sewage disposal would probably be less expensive than a contract, as sea-going ships of the type necessary for this work are not now available in Boston.

Representative samples of sludge from the three systems were analyzed by the Massachusetts Agricultural Experiment Station and the organization reported that the fat content is rather high and that the product is rather poorly balanced as a fertilizer for most crops, as it contains too much nitrogen as compared with the phosphoric acid and potash. For many hoed crops the product used at the rate of 1.5 tons per acre would be properly balanced by the use of about 1 200 to 1 400 lb of 16% super-phosphate and 240 to 300 lb of muriate of potash per acre.

Although the park departments of the city of Boston and the Metropolitan District Commission were not interested in the use of sewage sludge as fertilizer, provision should be made in designing the treatment plants for proper elevations and sufficient area for the preparation of sludge as fertilizer if it should become desirable.

SUMMARY

This study shows that the quantity of putrescible matter discharged into the harbor is not sufficient as yet to cause a nuisance resulting from the depletion of oxygen. Objectionable sleek areas, however, are often present over extensive portions of the harbor and, under certain tide and wind conditions, grease and other floating matters, characteristic of sewage, reach the shores. At times of considerable run-off, sewage overflows from the main trunk and lateral sewers and reaches shores used for bathing.

Bacterial examinations do not show the presence of bacteria characteristic of sewage pollution in the waters of the bathing beaches in such numbers as would warrant the prevention of bathing except in the vicinity of sewer overflows and at a few places where sewage is discharged directly into the harbor.

To correct these unsatisfactory conditions it will be necessary to discontinue the use of certain areas as bathing beaches or to make changes in the sewerage systems by moving the sewer overflows to points remote from the shore and by treating the sewage reaching the main outlets for the removal of matters that might reach the bathing places.

Although the discharge of sewage into Boston Harbor from the main sewer outlets may not as yet cause conditions dangerous to the public health, the nuisance from sleek and floating solids makes a change in the present methods of sewage disposal very desirable.

The most economical method seems to be the removal of suspended and floating solids in sedimentation tanks provided with skimming devices and the transportation of the solids and grease to sea in barges. More complete treatment and the extension of the present outlets at some future time, when larger sewage flow makes it necessary, are the logical steps in the disposal of the sewage of Metropolitan Boston.

The extension of the outlet systems by a tunnel to a site in the vicinity of The Graves without preliminary treatment of the sewage seems impracticable because of the high cost and because floating solids would probably still reach the neighboring shores.

DISCUSSION

E. SHERMAN CHASE,[7] M. AM. SOC. C. E. (by letter).—A number of important points relating to the sewerage and drainage of the Boston Metropolitan Area are presented in this excellent paper. Among these points are the distinct limits of capacity life of the drainage systems, in the increasing frequency of overflows as time goes on, the effect of suburban growth and transient populations upon the sewerage problems, the limitations of analytical data, standards of cleanliness for bathing beach waters, the relative economic merits of the proposed extension of the outlets, and the treatment of the sewage without the extension. The writer will limit himself to certain general points of public interest instead of discussing the more technical features of the paper.

From the very beginning of its organization, the Massachusetts State Department of Public Health (and its predecessor, the State Board of Health) has conducted intensive and noteworthy investigations into matters of pollution by sewage, and into methods of sewage treatment. The second annual report of the old State Board of Health, covering the year 1870, contains a most interesting letter from the chairman of the Board, Dr. H. I. Bowditch, entitled "Houses for the People, Convalescent Homes and the Sewage Question"—a somewhat curious combination. In this letter, in which several references are made to his visit to England and the continent in 1870, considerable space is devoted to the controversy, then raging abroad, over the earth closet system *versus* the water carriage system for removal and disposal of excretal matters—a controversy now forgotten.

It is also interesting to note, in light of the consideration given by the authors to the possible production of fertilizer from sludge obtained by treatment of the Boston sewage, the following paragraph from Dr. Bowditch's letter:

> "But there is one fatal defect of London and of all American sewage, and that is its waste.. Probably there is no such widespread recklessness of spendthrift prodigality anywhere so noticeable among civilized nations as this throwing away of such vast amounts of this most excellent of manures. We take thousands of tons from the earth annually, and totally ignoring Nature's law of economy, which declares that what has been once taken away must be returned again to earth, otherwise the earth itself will become improverished and will refuse to labor for us, I say totally ignoring this law, we squander an immense amount of really valuable property."

Dr. Bowditch was not the first nor the last to feel that way; but after sixty-nine years sanitary engineers have not yet reached the goal of economic use of sewage for its manurial value, as is evidenced by the very tentative way in which the authors discuss the possibility of utilizing sludge for fertilizer.

The interest displayed in the sewage problem by the State Board of Health undoubtedly was one of the reasons, at least, for the construction of the Main Drainage System of Boston and of the Metropolitan Systems. With the introduction of the Cochituate supply of water into Boston in 1848 there had been a marked improvement in sanitary conditions within the city; but objectionable conditions in the adjacent waters resulted from the discharge of sewage from sewers and drains at many points along the water-front. As time went on, the progressive improvements in the collection, interception, and discharge of sewage from the city and the metropolitan districts eliminated the more objectionable conditions, irrespective of the steady growth of population and industry. In fact (as the authors show), based on the criterion of the oxygen balance, the waters of Boston Harbor have ample capacity to assimilate much more sewage than now reaches them.

---

[7] Cons. Engr. (Metcalf & Eddy), Boston, Mass.

On the other hand, the fact that solids from the sewers can reach the shores, and the striking evidence afforded by Figs. 3, 4, and 11, show clearly that filthy conditions exist in parts of Boston Harbor. Furthermore, in spite of the difficulty in proving a specific health hazard from polluted waters, other than those used for water supplies, there is a definite trend of public opinion which is resulting in a demand for a standard of cleanliness consistent with ordinary good housekeeping. A similar trend has already been noted for some years in the water-supply field where the public now insists upon supplies of attractive qualities as well as safe from the standpoint of health. The authors have recognized this trend in their conclusions with respect to the undesirability of grease balls and other materials of sewage origin reaching the bathing beaches.

It must be remembered, however, that the correction of conditions of pollution costs substantial sums. In the last analysis the people can have just what they are willing to pay for, and when demands for improved conditions are made, those who make these demands must be prepared and willing to pay their share of the costs. The sanitary improvement of Boston Harbor is a type of public works project that might better be undertaken than many for which the taxpayers' money has been spent in recent years.

F. E. DeMartini,[8] Assoc. M. Am. Soc. C. E. (by letter).—In many respects this excellent paper could apply as a description of pollution in San Francisco Bay, in California. It may be of interest to outline briefly the situation there.

Until February, 1939, the untreated sewage of San Francisco was discharged to San Francisco Bay through twenty-eight outlets. Approximately half of these outlets discharged sanitary sewage and the others discharged storm water and varying quantities of sanitary sewage, depending upon the extent and intensity of rains. Three of the outlets—North Point, Bakers Beach, and Mile Rock—discharged the sanitary sewage from the largest proportion of the city's population. Local nuisances at some of the smaller outlets are critical, particularly in the ship channel parallel to Channel Street, and in Islais Creek. Sludge deposits have been extensive here in the past, resulting in extensive odors at low tide.

In 1932 a 1.0 mgd activated sludge sewage treatment plant was constructed by the Park Department, in Golden Gate Park, to reclaim sewage for irrigation of park lands and sludge for use as fertilizer. This was the first treatment plant of any importance built in the city.

---

[8] Associate Public Health Engr., U. S. Public Health Service, Cincinnati, Ohio.

In February, 1939, the 15.0 mgd Richmond-Sunset Sewage Treatment Plant started operation. At times of heavy rains and diluted sewage the plant is designed to handle peak flows of 55.0 mgd. This is a primary treatment plant for removal of grit, grease, and sludge. Chlorinating equipment is provided for the control of odors and disinfection of plant effluent. Briefly the factors leading to the construction of this first major treatment plant were as follows:

Disposal of raw sewage direct to the Bay waters resulted in (1) heavy pollution of a number of bathing beaches, (2) unsightly sleek areas, and (3) floating sewage solids and odors at many points along the bulkhead line on the water front. Practically all areas from which clams and oysters had been taken on the San Francisco side of the Bay were closed by the California State Department of Public Health in recent years due to increasing pollution of the Bay waters.

The complacent attitude of the city toward this pollution of San Francisco Bay underwent a gradual change starting about 1931. Invest gations by the city and State health departments were the principal stimuli to the new viewpoint. These investigations definitely indicated the gross pollution at Bakers Beach, Aquatic Park, and Yacht Harbor in the Marina. These recreational areas are used extensively by large numbers of people.

Conditions at China Beach were studied by the California State Department of Public Health in connection with a project to make the beach and adjacent lands a State and city park. Shortly thereafter a bacteriological study of the bay waters along the northerly and westerly shore line of the city (from pier 45 to the Funston Life Guard Station) was undertaken for one year by the San Francisco Department of Public Health. Both of these investigations indicated the serious extent of the pollution and the magnitude of the problem involved in its elimination. By 1934 interest had been aroused to such an extent that a board of consulting sanitary engineers was appointed by the city to study the problem of treatment and disposal of sewage from the city and county of San Francisco. In May, 1935, this board submitted a report and recommendations to the city.

A comprehensive plan was presented providing for the concentration of the city's sewage at a few points and for treatment of sewage before disposal into San Francisco Bay and the Pacific Ocean. In accordance with this plan sewage from the Marina District has been pumped to the North Point Outlet since 1937, and the Richmond Sunset Sewage Treatment Plant was completed in February, 1939. The sewage from Bakers Beach District, Richmond District, and Sunset District is treated at the new Richmond-Sunset Sewage Treatment Plant, prior to disposal into the Pacific Ocean at the Mile Rock Outlet. These developments will greatly improve conditions at a large number of small beaches and particularly at the Marina, Bakers Beach, and China Beach.

In addition to San Francisco there are a large number of communities discharging raw sewage to San Francisco Bay. A few places, among which are Burlingame, San Mateo, Palo Alto, and Petaluma, have built treatment plants, but there remain a large number of places that are seriously polluting the bay waters. There is no doubt that the program undertaken by the city of San Francisco, involving the expenditure of several million dollars, will have a salutary effect on the attitude of these communities toward elimination of their pollution load from the Bay.

Many details of the studies reported by the authors for Boston Harbor and the general recommendations for treatment and improvements are strikingly similar to those of the San Francisco Bay area.

A. M. RAWN,[9] M. AM. SOC. C. E. (by letter).—The authors' description of the investigation of the pollution of Boston Harbor and of corrective measures proposed raises a point or two in the writer's mind which, in connection with a problem of this nature, may merit some discussion.

It is not stated in the narrative whether the tubes from which data were gathered for preparation of the "isocols" in Fig. 9 were set immediately after the samples of mixed sewage and sea water were taken, or were iced and set later. The procedure here may have an important bearing upon conclusions because of the fact that sea-water plankton destroy bacteria quite rapidly, and time becomes an important factor in arriving at the number of tubes positive. This is well illustrated in Fig. 12. If the samples were set immediately after they were taken, the "isocols" shown in Fig. 9 may be said to represent a fairly true degree of pollution. However, if they were iced and set some hours later, a situation more aggravated than that shown in Fig. 9 might exist.

As an alternative to discharging sewage at the Graves, the authors propose plain subsidence works for the Boston Main and the North and South Metropolitan Sewerage Systems. It is not clear to the writer that construction of plain subsidence works at the points indicated by the authors, followed by the discharge of settling-tank effluent at present outfalls, will have any great effect upon the spread of contamination over the surface of Boston Harbor waters. In all probability, it will prevent the washing of objectionable material identified as of sewage origin on to the beaches; but the sewage discharged at or near the surface or through the sea outfalls, at present locations, will probably spread over and pollute as great an area within the harbor as is now the case with discharge of raw sewage. The fact that the harbor mud is polluted to the extent indicated in the authors' description seems to testify that a large proportion of the suspended material in the sewage settles quite promptly in the comparatively still harbor waters, as is to be expected. Such being the case, surface pollution, even at the present time, must be due largely to the spread of mixed sewage and sea water from which much of the suspended matter has settled. The writer's criticism is entirely invalid if plans contemplate the sterilization of the effluent prior to final disposal.

HARRISON P. EDDY, JR.,[10] AND SAMUEL A. GREELEY,[11] MEMBERS, AM. SOC. C. E. (by letter).—An excellent description of one of the earliest comprehensive sewerage systems, and of conditions in Boston Harbor after these works had been in service many years, is presented in this paper. The authors are to be complimented on the completeness and thoroughness of their work.

[10] Cons. Engr. (Metcalf & Eddy), Boston, Mass.

[11] (Greeley & Hansen), Chicago, Ill.

This area has been most fortunate in having available favorable tidal currents. Although the photographs in the paper give the appearance of an extremely unclean condition on the surface of the harbor waters from the Moon Head outlet, the intermittent discharge and the prompt removal and dispersion of the sewage by the currents have made possible the operation of this system for about fifty years without creating intolerable conditions. At the Nut Island outlet, the submergence of the outlets tends to offset the continuous discharge; and at Deer Island submergence, strong tidal currents, and proximity to the ocean are factors that have helped to reduce the unfavorable effects of pollution.

Under the provisions of a resolve of the Massachusetts Legislature of 1938, a special commission was appointed to make an investigation relative to the systems of sewerage and sewage disposal in metropolitan Boston. As a part of its investigation, this commission retained the writers' respective offices as consulting engineers to investigate and report upon the following two major subjects:

(*a*) Pollution in the Mystic River, and its major tributaries, and in the Charles River, and methods of correction; and

(*b*) Proposed methods of sewage treatment for the main outlets in Boston Harbor of the North and South Metropolitan Sewerage Districts and the Boston Main Drainage System.

In making their investigation and report, the engineers reviewed House Document No. 1600, December, 1936,[3] the testimony gathered by the special commission, and many other documents, and made personal observations of metropolitan Boston and the harbor, and of the main structures of the sewerage systems. Conclusions pertinent to the paper under discussion are as follows:

Mystic and Charles Rivers.—Objectionable conditions exist, at times, in the Mystic River, and its tributaries, and in the Charles River, due to pollution from sewage. This pollution occurs because, in times of storm, the capacity of the existing intercepting sewers is insufficient to carry away the sewage and storm water that are delivered to them, and the excess beyond their capacity is discharged into the streams through overflow channels provided for this purpose.

Correction of the objectionable conditions in the Mystic River, and its tributaries, and in the Charles River can be obtained best and most economically by the construction of storm overflow conduits of sufficient capacity so that no overflows into the streams will occur until the volume of storm water flowing in the sewers has provided sufficiently great dilution of the domestic sewage to prevent objectionable conditions from such overflows. If these recommendations are followed, it should no longer be necessary for Boston and a few other municipalities to separate storm water and sewage in areas tributary to the Charles River, as now required, when new sewers are built or old sewers are replaced.

The existing Mystic Valley sewers were relieved by the construction, in 1936 and 1937, of the North Metropolitan relief sewer from Reading, Mass., to a point a short distance below Craddock Dam in Medford, Mass. This relief sewer is now (1940) being extended to the East Boston pumping station; and it is proposed by the consulting engineers that the North Metropolitan relief sewer be extended from East Boston to Deer Island. The estimated cost of construction of the storm overflow conduits, pumping stations, and force mains recommended, including the extension of the North Metropolitan relief sewer to Deer Island, is $14 695 000.

Pollution of Boston Harbor.—To aid them in reaching a conclusion as to the limiting effect of sewage in Boston Harbor upon the use of the waters, and as to the need for sewage treatment, the consulting engineers have adopted a standard for the desirable condition of the harbor waters, after consideration of standards proposed and adopted elsewhere and of the existing sanitary conditions. They have assumed that, for the bathing beach waters of the harbor, a single *B. coli* index of 1 000 per 100 cc is a warning that excessive contamination may be present at times, and that an average index in excess of 3 000 *B. coli* per 100 cc shows that the waters may be dangerous to the public health.

In examining the bacteriological analyses made by the Massachusetts Department of Public Health during the investigations of Boston Harbor in 1929–1930, and 1935–1936, the consulting engineers made a large number of charts showing the distribution of the *B. coli* index throughout the harbor. One of these, Fig. 13, has been selected as giving a representative picture of the average or general bacteriological condition of the harbor. It shows the average and maximum *B. coli* indices of all samples collected at each sampling station during the 1935 investigation, as well as the areas where the *B. coli* index was probably in excess of 3 000 per 100 cc and those where there was a probable *B. coli* index between 1 000 and 3 000 per 100 cc.

It is of interest to note that, in general, the number of days on which samples were taken was five to ten at each station during each of the years 1935 and 1936. During 1935, the prevailing winds on the sampling days were from the west and southwest, and during 1936 they were from the east and southwest. The higher *B. coli* indices occurred when the wind was blowing from the north and east. There is a possibility, therefore, that if all samples had been taken on days when the wind was blowing from the north or northeast, the average of the analyses would have shown much higher *B. coli* indices for the shore waters.

The consulting engineers have come to the conclusion that the bacterial content of the shore waters of the harbor, as evidenced by the *B. coli* index, in some places is at times higher than what is generally considered a reasonable upper limit for the safety of bathing beach waters. Furthermore, the proximity to the shore, of harbor waters that are highly contaminated with raw sewage from the outlets, is a potential source of excessive bacterial pollution which is certain to increase in the future. In addition, the stirring up of the mud at the bottom of the harbor, which was found to contain many more bacteria characteristic of pollution than did the water at the surface, by strong onshore winds, is a potential source of excessive bacterial pollution. conditions are potentially dangerous to the public health to such an extent that corrective and preventive measures should be undertaken as soon as practicable by the construction of sewage treatment works.

Sewage Treatment Plants.—The proposed method of sewage treatment is essentially the same at each of the three main outlets, and comprises the following principal elements: Fine racks, grit chambers, aero-chlorinating tanks, sedimentation tanks, sludge storage tanks, equipment for disposal of sludge at sea, and chlorination equipment.

It is contemplated that the sedimentation tanks will be equipped with mechanical means for removal of sludge, grease, and floating solids. In order to increase the proportion of grease that can be removed by skimming, it is deemed advisable to aerate the sewage and apply a small quantity of chlorine to it. It is planned to burn the scum in suitable incinerators. The projects include the disposal of sludge by barging to sea, where it may be discharged without causing complaint. The excessive bacterial pollution of harbor and shore waters during the season of recreation can be prevented by disinfection of the sewage with liquid chlorine.

The total estimated costs of construction of the three proposed plants, with capacities estimated for 1955, together with the estimated population and the annual average quantity of sewage tributary to each of them in that year, are given in Columns (2), (3), and (4), Table 13. On the assumption that 20-yr, 2¼% serial bonds of equal annual retirement payments are issued in 1941, the total annual costs of the three projects, as of 1943, are estimated to be as shown in Column (7), Table 13.

GEORGE A. SOPER,[12] M. AM. SOC. C. E. (by letter).—Every one will be grateful to the authors of this valuable paper for putting on record the important results of the investigations of the pollution of Boston Harbor. Had the studies made of New York Harbor been presented to the Society in suitable papers at the time they were made, there is little doubt that they would have been of much greater value to the profession. As it is, the work of the New York investigators, up to 1914, must be sought in the three volumes of the Metropolitan Sewerage Commission, which were published in 1910, 1912, and

---

[12] Cons. Engr., New York, N. Y.

1914, and as these editions were limited, the information is not always to be found even in important libraries.

The conditions attending the discharge of sewage into Boston Harbor have been of much interest in connection with the investigations which have been made of New York Harbor.

The New York Bay Pollution Commission, which existed between 1903 and 1906, took careful account of the conditions as they were reported in the official reports and looked upon them as a warning of conditions which should never be allowed to occur in the harbor of New York.

Some years later the members of the Metropolitan Sewerage Commission of New York went to Boston and visited the Deer Island, Moon Island, and Peddocks Island outlets, to see for themselves the results of discharging sewage under the three methods used. The reasons for the works and what they were intended to accomplish had been made familiar to them through reports and correspondence. The chief engineer of the Massachusetts State Board of Health was invited to consult on the New York work, because of his familiarity with the disposal of the sewage of Boston and vicinity.

Not being able otherwise to obtain all the information wanted, the Metropolitan Sewerage Commission sent its floating laboratory, *Quadrant*, to Boston to make studies, especially of dissolved oxygen, by the identical method which had proved successful in the Commission's hands in studying the digestive capacity of New York Harbor for sewage.

Throughout its eight years of existence, the Metropolitan Sewerage Commission recognized that it would not be necessary nor practicable to keep all sewage out of New York Harbor, but that the harbor had a large capacity for assimilating sewage, harmlessly and inoffensively, provided the principles under which the digestive capacity was utilized were thoroughly understood and skilfully employed.

Proper diffusion was indispensable to digestion and many experiments designed to "throw light" upon this subject were made in the laboratory, in large tanks courteously set aside in the New York Aquarium by the New York Zoological Society, and by means of properly equipped boats, and pontoons filled with sewage on Long Island Sound and in various parts of New York Harbor. There were parts of the harbor itself which were looked upon as affording exceptional opportunities for investigating the phenomena of diffusion and digestion, and as these had the merit of practical application, they received very careful attention. Before the investigations of the Metropolitan Sewerage Commission were concluded, the entire harbor of New York came to be looked upon in the light of a great laboratory where experiments on a huge scale were being conducted.

ARTHUR D. WESTON,[13] AND GAIL P. EDWARDS,[14] MEMBERS, AM. SOC. C. E. (by letter).—In closing the discussion, attention is called to the remarks by Mr. Rawn, in which the question has been raised as to the effect on the bacterial counts of the length of time which elapsed between the collection of the samples and the "setting" of the samples, the results of which are shown in Fig. 9.

---

[13] Chf. Engr., Dept. of Public Health, State of Massachusetts, Boston, Mass.

[14] Prin. San. Chemist, Wards Island Sewage Treatment Plant, Dept. of Public Works, City of New York, Wards Island, N. Y.

Laboratory records show that, of all the samples collected in 1936, 47% of the fermentation tubes were set the same day that the samples were collected, 50% were set the next day (usually in the forenoon), and only 3% of the samples were more than 24 hr old before setting. Confirmed tests were made on all positive fermentations.

The close correlation between the results of the bacterial examinations and the sanitary surveys would lead one to believe that any error from delay in setting has not affected the findings seriously, and to all practicable purposes these results are a fair indication of the coliform density of the waters in various parts of Boston Harbor. Undoubtedly, the bacteria density of tidal waters is affected by the plankton, but the laboratory of the Massachusetts State Department of Public Health has no definite information as to such relationship. Accordingly, without supporting data the effect of the plankton is speculative. Regardless of the killing, by plankton or other causes, one would have to assume that, if the killing were as Mr. Rawn states, the harbor waters inside of the point of outfall on the outgoing tide would be nearly free from coliform organisms. Fig. 12 shows that most of the killing is done in the first 2 hr and that there is little effect after that period of time. An examination of Table 11 shows that in accordance with laboratory experiments conducted with sea water and 0.5% of sewage the same number of coliform organisms was present in the sample at the end of 24 hr as at the start. This number diminished to practically 0 at the end of 96 hr; but in the case of the 1% sewage with sea water, the reduction was from 500 to 100 in 24 hr and again to about 0 at the end of 96 hr. With 1.5% sewage added to sea water the reduction was from 1,000 to 100 in the first 24 hr, 50 at the end of 48 hr and 0 at the end of 96 hr. The results of tests made in 1935 by Paul J. Beard and Niel F. Meadowcroft of Stanford University, at Stanford University, Calif., show that 60% of *Escherichia Coli* survive for a period of one day and at the end of ten days more than 3% are still present in the water.[15] Undoubtedly there is a need for further research in the matter of the effect of plankton or other causes on coliform organisms in sea water.

It should be borne in mind that, in conducting any studies such as that in Boston Harbor, many inaccuracies can enter the study. For example, with the use of one boat a number of hours may elapse between the collection of some samples; and during this period of collection change of winds and variations in tidal conditions may play an important part. Furthermore, it should be stated that the results shown illustrate only the conditions found at the time the samples were collected; undoubtedly at other times objectionable conditions may be more pronounced. Taking all of these things into consideration, the writers feel, therefore, that the results illustrate, unusually well, the conditions disclosed by the sanitary survey.

Relative to the effect of partial treatment of the sewage before it is discharged into the harbor, on the bacterial content of the water of the harbor, it should have been stated that the recommendations do provide for chlorination of the settled sewage.

The various discussions by Messrs. Chase, Eddy and Greeley, DeMartini, Rawn, and Soper are greatly appreciated.

SIMPLIFIED WIND-STRESS ANALYSIS OF TALL BUILDINGS

BY OTTO GOTTSCHALK,[1] ESQ.

WITH DISCUSSION BY MESSRS. SAMUEL T. CARPENTER, CHARLES B. WINICK, AND OTTO GOTTSCHALK.

SYNOPSIS

The simple method of analysis explained herein is based on experiments to determine visible model deformations[2] and on studies leading to a purely geometrical interpretation of them.[3] The subject has been outlined by the writer several times since 1934[4] in computing inflection points under vertical loads. A structural frame is analyzed by subjecting it to given displacements. The resulting deformations are multiplied by the given loads in order to obtain the stresses.[5] This process of interpreting the model experiment directly avoids the need of solving innumerable abstract equations, by introducing only the simple expressions for the deformation curves. For one-story portal frames, with relatively stiff beams and fixed or hinged column supports, simple formulas were developed by the writer in 1932.[6] The method presented herein applies to frames of any number of stories with any number of bays and with beams and columns having any constant section.

NOTATION

The letter symbols used in this paper are defined herein when first introduced in the text. They are consistent with those introduced in a prior paper[3] and conform essentially with American Standard Symbols for Mechanics, Structural Engineering, and Testing Materials,[7] compiled by a committee of the American Standards Association, with Society representation and approved by the Association in 1932.

THEORY

In order to compute stresses due to wind, earthquake, or other lateral loads, the structures must be observed to determine the lateral displacements of the floors. The resistance of a column to that displacement (that is, the share of the total horizontal loads that it will absorb) is proportional to its stiffness multiplied by the sum of the relative resistance to rotation of all the members meeting at a joint. For lateral loads geometrical analysis may be greatly simplified because any approximation can be introduced that will affect, almost equally, all the members of the part of the frame under consideration.

Let k = the stiffness, $\frac{I}{h}$, of Column $A\,B$; I = the moment of inertia of the column, of height, h; m = a ratio of end rotations such that[8] $m = \frac{f}{f'} = \frac{0.5\,k}{S_B + k}$ and $m' = \frac{f'}{f} = \frac{0.5\,k}{S_A + k}$; S = a relative stiffness value such that the resistance to rotation of End A of a column is:

$$S = (1 - 0.5\,m)\,k \qquad (1a)$$

and, the resistance to rotation of End B, is:

$$S' = (1 - 0.5\,m')\,k \qquad (1b)$$

f = the intercept at End A of the tangent to the elastic curve at End B; thus,

$$f = \theta_A\,h \qquad (2a)$$

and,

$$f' = \theta_B\,h \qquad (2b)$$

θ = the angular rotation of the column relative to the final direction of its axis; thus θ_A is the rotation at End A (Fig. 1), with respect to Line $A\,B'$, and θ_B is the rotation at End B' with respect to Line $B'\,A$; and the height of the point of contraflexure is:

$$h_A = \frac{h\,(2 - m)}{3\,(1 - m)} \qquad (3)$$

Furthermore:[9]

$$\frac{f}{\Delta} = \frac{-\,S_B}{S_B + k} + \frac{m\,S_A}{S_A + k} \qquad (4a)$$

and,

$$\frac{f'}{\Delta} = \frac{S_A}{S_A + k} - \frac{m'\,S_B}{S_B + k} \qquad (4b)$$

and the force, P, necessary to produce Displacement $\Delta = 1$, is:

$$P = \frac{6\,E\,k\,(f' - f)}{h^2} \qquad (5)$$

---

[8] *Transactions*, Am. Soc. C. E., Vol. 103 (1938), p. 1022, Equations (1) and (2).

[9] *Loc. cit.*, Equations (11), (12), and (15), pp. 1025, 1027.

In Equation (5) $\frac{6E}{h^2}$ is equal for all the columns of any one story. The horizontal resistance, therefore, against a unit side-sway (that is, the percentage that each column of a story absorbs of a horizontal force acting upon the floor above) is in proportion to $k\,(f' - f)$. None of the many approximate methods of wind-stress analysis of frames proposed heretofore yields safe results, unless it takes that quantity into consideration. The complexities introduced by poor proportioning of columns were emphasized by George E. Large, Assoc. M. Am. Soc. C. E., and Samuel T. Carpenter, Jun. Am. Soc. C. E., in 1934.[10]

Equations (4) may be considerably simplified for typical stories. In Fig. 1, when Column $A\,B$ is fixed at one end (that is, when $S_B = \infty$) $m = 0$ and $S = (1 - 0.5\,m)\,k = k$ at the other end.[3] As an opposite extreme assumption, that is, when $S_B = k$, the corresponding values are: $m = 0.25$ and $S = (1 - 0.5 \times 0.25)\,k = 0.875\,k$. The range of values of m and $\frac{S}{k}$, then, is small. For typical stories, therefore, it may safely be assumed that the conditions of rigidity at the tops of columns are sufficiently similar to those at the bottom so that, in all structural frames, for lateral movements of floors, $m = 0$ and $S = k$. Simplifying Equations (4) accordingly:

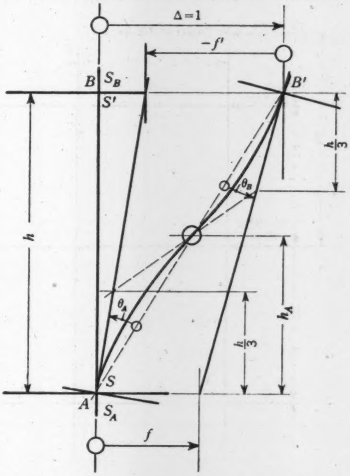

FIG. 1.—DEFORMATION OF A COLUMN DUE TO UNIT DISPLACEMENT OR SIDE-SWAY, AT TOP.

$$\frac{f}{\Delta} = \frac{-\,k_B}{k_B + k} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6a)$$

and,

$$\frac{f'}{\Delta} = \frac{k_A}{k_A + k} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6b)$$

in which k_A and k_B, instead of S_A and S_B are the sum of the stiffness, $k = \frac{I}{h}$, of the structural members joining Line $A\,B$ at Points A and B, respectively. For the purpose of the present analysis, therefore, one may read the assumed k-values directly instead of computing the value of S first.

Note that, in Equations (6), f and f' have different signs and, therefore, they must be added in Equation (5).

As a further admissible simplification, when analyzing any one typical story, the designer may disregard the columns above and below that story.

---

[10] *Engineering News-Record*, May 17, 1934, p. 637.

With all those simplifications, which affect the deformations of all columns in nearly equal proportion, results have proved to be quite close to those found by the "exact" abstract analysis—safely within 5% for shears and reactions, and little more for bending moments when assuming inflection points at the middle of the column heights of typical stories.

FIG. 2.—DIAGRAM OF TYPICAL STRUCTURAL FRAME

Fig. 2 is the diagram of the ground floor and two typical upper stories of a structural frame, showing the assumed k-values $\left(\frac{I}{L}\right.$ in beams and $\frac{I}{h}$ in columns$\left.\right)$, all of which are different. At the ground floor, on both sides of the fixed base of the interior and exterior columns $k_A = \infty$, and, therefore, $\frac{k_A}{k_A + k} = 1$. At the nth and $(n + 1)$th floor horizontal wind loads, $P_n = 32.4$ kips and $P_{n+1} = 28.8$ kips, may act. (The kip, or "kilo-pound" equals 1 000 lb.)

Each story and, within each story, each bay are next analyzed separately by subjecting the upper beams of the nth story (see Fig. 3(a)) to a side-sway,

$\Delta = 1$. Interior columns always form part of two adjacent bays, and interior beams, part of two stories. The height, h, is constant for all columns and, as the designer is only concerned with relations between the deformations of the several columns, he need simply write at every angle the $\dfrac{k_B}{k_B + k}$-values at the upper beams and the $\dfrac{k_A}{k_A + k}$-values at the lower beams. For example, at Point D at the top floor $(n + 1)$, $\dfrac{5}{5 + 5.5} = 0.48$, and at the next floor below (n), $\dfrac{12}{12 + 5.5} = 0.69$; and for Column D the sum of resistance at the nth story, $0.48 + 0.69 = 1.17$.

(b) GROUND FLOOR

FIG. 3.—RELATIVE RESISTANCE OF BUILDING COLUMNS TO UNIT LATERAL DISPLACEMENT (SIDE-SWAY), BY THE COLUMN SHEAR METHOD

Line 6, Fig. 3(a), gives the total rotations $(\theta_A - \theta_B)$ of the columns at the left and at the right sides of the given bay, and Line 7 gives the values of $k\,(\theta_A - \theta_B)$. The sum of the values in Line 7 is 31.67 and, consequently, the relative resistance values, shown in Line 8, are $\dfrac{3.81}{31.67} = 0.121$; $\dfrac{3.94}{31.67} = 0.125$; $\dfrac{3.88}{31.67} = 0.123$; etc. In Line 9 the relative resistance of the columns of the nth story to the lateral load, $P_n = 1$, at the top, equals 0.121, $0.125 + 0.123 = 0.25$, etc. Similar values for the columns of the $(n + 1)$ story, for a lateral load of $P_{n+1} = 1$ at the top, have been computed as 0.135, $0.125 + 0.140 = 0.265$, $0.198 + 0.217 = 0.415$, and 0.185.

At the ground floor (Fig. 3(*b*)) all the columns are fixed (that is, $k_A = \infty$). Therefore, $\theta_A = \dfrac{k_A}{k_A + k} = \dfrac{\infty}{\infty + k} = 1$ (Line 15, Fig. 3(*b*)). In Line 17, $(\theta_A - \theta_B) = 2.62$, 2.99, 2.87, and 2.57; and in Line 18, $k\,(\theta_A - \theta_B) = 2.62 \times 5 = 13.1$; $2.99 \times 7 = 20.9$; $2.87 \times 11 = 31.6$; and, $2.57 \times 9 = 23.1$—total 88.7. Every column then absorbs of a lateral load, $P_1 = 1$, at the top in the proportion: $\dfrac{13.1}{88.7} = 0.147$; $\dfrac{20.9}{88.7} = 0.236$; $\dfrac{31.6}{88.7} = 0.357$; and, $\dfrac{23.1}{88.7} = 0.260$ (see Line 19).

For the purpose of computing stresses the designer needs to know the location of the inflection point in the columns, where the foregoing thrusts are assumed to act. For typical stories those points may be assumed, closely enough, to act at mid-height. (Hale Sutherland and Harry L. Bowman,[11] Members, Am. Soc. C. E., propose values that are slightly different, as a result of studies of a large number of examples.) For the ground floor, with columns fixed at the bottom, conditions at the top and bottom vary greatly and the points of inflection are to be computed at a distance, h_A (see Fig. 1), from Point *A*, equal to:

$$h_A = \frac{h\left(2 - \dfrac{\theta_B}{\theta_A}\right)}{3\left(1 - \dfrac{\theta_B}{\theta_A}\right)} \qquad \text{.......................(7)}$$

In Fig. 3(*b*), $\dfrac{h}{3} = \dfrac{18}{3} = 6$ ft; and, at Column *A*: $\dfrac{\theta_B}{\theta_A} = \dfrac{-\,0.62}{2.00} = -\,0.31$. The height, h_A, to the point of contraflexure is $6 \times \dfrac{2.31}{1.31} = 10.6$ ft. For Column *B*: $\dfrac{-\,(0.53 + 0.46)}{2.00} = -\,0.50$ and $h_A = \dfrac{6 \times 2.5}{1.5} = 10$ ft. Similarly, at Column *C*: $h_A = \dfrac{6 \times 2.44}{1.44} = 10.2$ ft and, at Column *D*: $h_A = \dfrac{6 \times 2.29}{1.29} = 10.7$ ft.

Having analyzed the structure in this manner the horizontal thrust or shear in the columns in the *n*th floor is obtained as follows (Line 4, Fig. 3(*a*)): $T_A = 32.4 \times 0.12 = 3.9$ kips; $T_B = 32.4 \times 0.25 = 8.1$ kips; $T_C = 32.4 \times 0.43 = 13.9$ kips; and, $T_D = 32.4 \times 0.20 = 6.5$ kips. Assuming that the inflection points are at the mid-height of the columns, the bending moments at the tops will be $8.0 \times 3.9 = 31.2$ kip-ft; $8.0 \times 8.1 = 64.8$ kip-ft; $8.0 \times 13.9 = 111.2$ kip-ft; and, $8.0 \times 6.5 = 52.0$ kip-ft, respectively.

The vertical reactions in the columns of the *n*th floor, produced by the wind load at the *n*th floor, may be obtained, assuming that the several bays of the story must resist the overturning wind moment of $28.8 \times 7.0 + 32.4 \times 8.0 = 460.8$ kip-ft. As indicated in parentheses in Line 9, Fig. 3(*a*), the part of the horizontal thrust absorbed by the three bays, respectively, is 0.25, 0.31, and 0.44; and, consequently, the shear within the bays is $\frac{0.25 \times 460.8}{15} = 7.7$ kips; $\frac{0.31 \times 460.8}{20} = 7.1$ kips; and, $\frac{0.44 \times 460.8}{25} = 8.1$ kips. The reaction at each of the four columns is: $R_A = -7.7$ kips; $R_B = 7.7 - 7.1 = 0.6$ kips; $R_C = 7.1 - 8.1 = -1.0$ kips; and, $R_D = 8.1$ kips.

---

[11] "Structural Theory and Design," by Hale Sutherland and Harry Lake Bowman, N. Y., John Wiley & Sons, Inc., 1930, Method C, p. 207.

When only column reactions or beam moments are wanted it may be preferable and sufficiently accurate to analyze the beams directly for shear as demonstrated in Fig. 4. The top beam of the *n*th story is assumed to be deflected laterally a distance, Δ, assuming for convenience that $\Delta = h$, with respect to the beam below. The approximate relative rotations at the four columns are thus determined as shown. In Line 2, Fig. 4: $\theta_A = 0.46$; $\theta_B = 0.30$; $\theta_C = 0.46$; and, $\theta_D = 0.53$. These values may be assumed positive on the right and, therefore, negative on the left of the columns. Note that those rotations are only relative values and must not be used separately for the analysis of any beam.

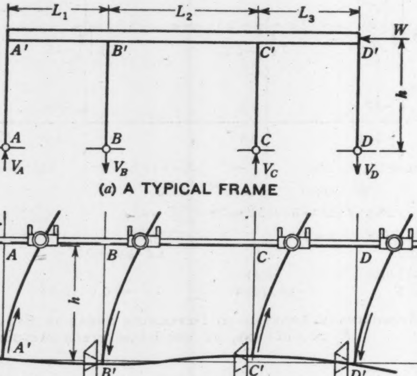
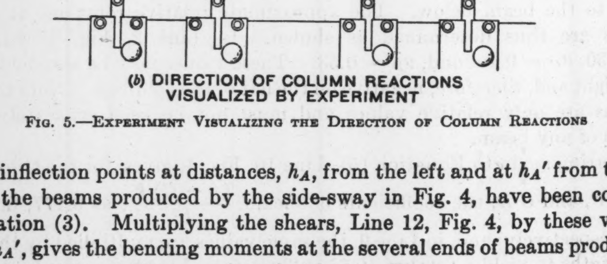
FIG. 4.—APPROXIMATE ANALYSIS TO DETERMINE SHEAR IN BEAMS AND REACTIONS, *R*, IN COLUMNS, BY THE BEAM SHEAR METHOD

Referring again to Equation (5), Line 10, Fig. 4, gives, for the three beams, *A B*, *B C*, and *C D*, the coefficients of shears, $\frac{(f - f')\,k}{L^2}$, as 0.177, 0.152, and 0.198, respectively; and, in Line 9, the same values are multiplied by the several span lengths to yield a total of 10.65. Therefore, Line 9 represents the sum of the moments of the shear at the ends of the beams, equal to the moment of wind loads with respect to the Axis *A B C D*, which (as computed previously and entered in Line 11, Fig. 4) is 460.8 kip-ft. Since $\frac{460.8}{10.65} = 43.3$, the shear in the several openings is, as indicated in Line 12: 43.3 × 0.177 = 7.7; 43.3 × 0.152 = 6.6; and, 43.3 × 0.198 = 8.6 kips.

The reactions at Columns A, B, C, and D, corresponding to the nth floor, are as shown in Line 13, Fig. 4, as follows: $R_n = -7.7$; $7.7 - 6.6 = 1.1$; $6.6 - 8.6 = -2.0$; and, 8.6 kips, respectively. These reactions would have to be computed in a similar manner for all the floors above, and added from the top floor down to the nth floor to obtain the total column pressure, but generally it will be close enough to increase the reactions obtained for the nth floor in relation to total moments, as follows: Suppose that the center of gravity of the wind load (32.4 kips) at the nth floor is at 63 ft above the nth floor, as shown in Fig. 2; then the reactions, R_n, obtained previously (see Line 13, Fig. 4) must be multiplied by $\frac{32.4 \times 63}{460.8} = 4.43$, making the total reactions, R_t, in the columns of the nth floor, due to wind pressure (see Line 14) $= 4.43 \times 7.7 = -34.1$; 4.9; -8.9; and, 38.1 kips.



(a) A TYPICAL FRAME



(b) DIRECTION OF COLUMN REACTIONS VISUALIZED BY EXPERIMENT

FIG. 5.—EXPERIMENT VISUALIZING THE DIRECTION OF COLUMN REACTIONS

The inflection points at distances, h_A, from the left and at h_A' from the right ends of the beams produced by the side-sway in Fig. 4, have been computed by Equation (3). Multiplying the shears, Line 12, Fig. 4, by these values of h_A and h_A', gives the bending moments at the several ends of beams produced by wind load at the nth floor, as given in Line 15, Fig. 4.

It will be noted that the reactions in the columns are generally positive and negative, alternately, and not (as frequently assumed in wind-stress analysis) positive at one side of the center of the frame and negative on the other side. Such arbitrary assumptions may lead to considerable error, especially when the lengthening and shortening of columns is being taken into consideration.

The simple experiment in Fig. 5 will illustrate how the signs for column pressures may alternate. Fig. 5(*a*) shows a typical portal frame and Fig. 5(*b*) is the model reproducing it, held upside down at the top of the columns. The column bases are held at their original distance from each other by means of clamps fixed on a sliding rod. When the rod is pushed to the right the first and the third columns of the model are being pulled upward and the second and fourth columns are pushed down, indicating pull and compression in alternate columns, respectively.

For very tall buildings the secondary stresses from the shortening of compressed columns and the lengthening of expanded columns, may be of interest. Suppose that there is a possible average of 6 000 lb per sq in. computed stress due to wind loads alone in exterior steel columns (modulus of elasticity = 30×10^6), the column would shorten or lengthen $\frac{2}{10.000}$ or, 0.24 in. in every 100 ft. Eventually, part of this deformation will be absorbed by the masonry.

When designing very tall frame structures, therefore, it may be convenient to compute column stresses by either one of the methods shown in Figs. 3 and 4 and correct the column loads according to the change of length to be expected, applying Fig. 1 and Equation (5). As an example, assume that, at a great height, in a tall building the leeward column shortens 1 in. with respect to the nearest interior columns; and, assume a restraint equivalent to 50% fixation at both ends of the adjoining beam: $f - f' = 1$ in. If that beam has a length of $L = 200$ in. and a moment of inertia of $I = 1\,000$ in.^{4}, making $k = \frac{1\,000}{200} = 5$ in.^{3}, Equation (5) yields:

$$P = 6 \times 30\,000\,000 \times 5 \times \frac{1}{200^2} = 22\,500 \text{ lb} = 22.5 \text{ kips}$$

which is the amount by which the load on the exterior column must be decreased and the load on the interior column increased for a 1-in. difference of level.

CONCLUSION

The elementary simple methods, derived from the visible model experiment, which are presented for immediate application in Figs. 3 and 4, should prove a convenient tool in structural design. By merely starting from actual $k\left(=\frac{I}{L}\right)$-values of any frame the designer can take into account the practical peculiarities encountered in the field. That is not possible with prior methods of approximation, nor with the abstract mathematical treatments, except, perhaps, for the simplest of structures. Fig. 3 especially presents the only procedure known to the writer of analyzing, conveniently, those frequent cases of application in the field, where the stiffness value, $k = \frac{I}{L}$, of some of the sustaining members of a skeleton is relatively infinite, such as reinforced concrete stair-cases and elevator shafts.

The "column shear method," demonstrated in Fig. 3, may be applied to advantage generally. The "beam shear method" in Fig. 4 requires even less work and is recommended for quick calculation of reactions in columns subjected to wind pressure and for revising the design of structural frames to take account of possible differences of levels produced in tall columns by horizontal loads, impacts, or unequal changes of temperature.

DISCUSSION

Samuel T. Carpenter,[12] Assoc. M. Am. Soc. C. E. (by letter).—The statement in the "Synopsis" that the author has presented a simple method of analysis is true, the writer having applied the method satisfactorily to several cases with a great deal of ease, but not without first studying, thoroughly, the principles[3] upon which it was based.

Equation (5) expresses the horizontal resistance of a column for a total lateral displacement of $\Delta = 1$. Not only is this equation important in the analysis, but it may be of equal importance in making the structural design, if the designer places any importance in the final elastic action of his structure and the achievement of initially assigned column and girder shears. Although it is impracticable always to provide the required value of k for the columns of a bent, it is usually practicable to provide approximately the correct stiffness for the girders framing to the columns. For example if, by the cantilever method, the designer has assigned a value for shear equal to P to Column A of the bent shown in Fig. 3, and has provided a column of a stiffness k, then $(f' - f)$ should equal $\frac{h^2 P}{6 E k}$. This criterion, plus Equations (6*a*) and (6*b*), when used in conjunction with a desired story deflection equal to Δ, should yield approximately correct values of stiffness for the adjacent girders.

For a case of building design Δ may be controlled by the designer to be $0.002\,h$, or any other desired value. In most cases of regular story framing, and for an exterior column, k_A could be assumed equal to k_B, making $(f' - f)$—from a simplification of Equations (6*a*) and (6*b*)—equal to $\frac{2\,k_A\,\Delta}{k_A + k}$. Then

$$P = \frac{6\,E\,k\,\Delta}{h^2}\left(\frac{2\,k_A}{k_A + k}\right) \qquad (8)$$

from which k_A could be found and would be approximately the desired stiffness of the girders connecting to the exterior column. A similar treatment could be used in designing the girders framing to the interior columns. It is apparent, of course, that the girder selections must also depend on maintaining a safe combined unit stress.

The designing of a tall building to achieve a certain elastic action was pointed out and described by H. V. Spurr,[13] M. Am. Soc. C. E. Later, in a paper[14] describing the analysis of a model, designed to check experimentally the action of a structure elastically designed, it was shown that such a design satisfied not only the required deflection but yielded experimental shears equal to previously assigned values. This latter paper also deals with the practical problems of correct designing in the lower stories and around points of structural irregularity. The writer believes that the author's method would be thoroughly applicable in design, but would be somewhat dependent upon the choice of correct lengths of columns and girders for the calculation of stiffness.

[14] "Tests and Design of Steel Wind Bents for Tall Buildings," by George E. Large, Assoc. M. Am. Soc. C. E., Samuel T. Carpenter, Jun. Am. Soc. C. E., and Clyde T. Morris, M. Am. Soc. C. E., *Bulletin No. 93*, The Engineering Experiment Station, Ohio State University, 1936.

The author shows that the secondary stresses, from the shortening and lengthening of columns by the wind stresses beyond the points allowing planarity of the floor joints, are of importance. It has been shown elsewhere[15] that in a tall building, the adjustment of column stresses is not serious in the upper stories, but of considerable importance in the lower stories, due to the accumulation of girder shear corrections. The method presented by the author would appear to be applicable in the adjustment of column stresses and the calculation of the secondary girder shears. However, it should be the duty of the designer, particularly in the taller building, to assign correct values of direct stress and shear in his original design, where possible, and then to design the structure so that they are obtained, thus eliminating this adjustment.

CHARLES B. WINICK,[16] ASSOC. M. AM. SOC. C. E. (by letter).—An able and simplified method of computing wind stresses is presented in this paper. Designers of buildings have long been in search of a simple method of obtaining shears, reactions, and bending moments due to wind loads for the various members of a building frame. Since the development of the Hardy Cross method[17] of moment distribution, extensive literature has been written on the subject. The application of the Cross method to obtain shear, reaction, and moment distribution due to wind loads on a building frame is relatively simple, especially if it is not extended to a high degree of accuracy. Numerous attempts have been made, more or less successfully, to obtain "accurate analyses" by some one or other "exact method." The writer is cognizant of the fact that the problem of stress distribution due to wind loads, even in a relatively simple building, does not lend itself readily to an exact solution. Flooring, partitions, stair openings, elevator shafts, concrete slabs, and numerous other factors invariably affect the stiffness of the structure. It is questionable, therefore, whether the time consumed in arriving at a so-called accurate solution, through the application of some "exact method," is justifiable and consistent with the accuracy required in a problem of such uncertain nature. The method as outlined by Mr. Gottschalk is sufficiently accurate to serve the purposes of almost any type of building when the moments of inertia of the several members involved are constant. A designer familiar with building structures can readily apply this method, and it is questionable whether results obtained by any other complicated "exact method" are superior to it.

The writer has undertaken to recompute the values given by the author, as shown in Figs. 2 and 3, with the aim of applying some "short cuts" wherever possible, and has found some interesting results. For this purpose, all computations are referred to Fig. 2. The writer has found it difficult to refer to Fig. 3 because it is not consistent with Fig. 2. Thus, the $(n + 1)$th story of Fig. 3 corresponds to the nth story of Fig. 2, etc. Reference to both Figs. 2 and 3 leads to considerable confusion and, as a substitute, the writer developed

separate tables for each analysis of each floor shown in Fig. 2. All values obtained and their methods of computation were arranged as shown, for example, in Table 1. The complete computations were made in logical order, with painstaking care. Before discussing some of the results it is well to emphasize the fact that the method is only approximate but sufficiently accurate for all practical purposes.

As the author states, when $S_B = \infty$, $m = 0$ and $S = k$; and, when $S_B = k$, $m = 0.25$ and $S = 0.875$. The range of values of m, therefore, is between 0 and 0.25; that of $\frac{S}{k}$ is between 0.875 and 1.0; and, therefore, the assumptions that—(*a*) The conditions of rigidity at the tops of columns are sufficiently similar to those at the bottom for a typical story, and (*b*) that, in all structural frames, for lateral movements of floors, $m = 0$ and $S = k$—will produce a small error in the final computation of the column shears, moments, and reactions.

As shown in Fig. 3, the relative resistances of building columns of a typical floor, to unit lateral displacement, were computed by utilizing both the upper and lower floor beams which the column spans. The writer computed similar values by using either the upper or lower floor beams and also the beams of both floors, with remarkable agreement in results.

Table 1 shows the relative resistance values of building columns for the $(n + 1)$th story to a lateral load of $P_{n+1} = 1$ at the top as shown in Fig. 2 using upper floor beams only. The first line shows the k-values equal to $\frac{I}{h}$ (or $\frac{I}{l}$, as the case may be). The second line gives the $(\theta_A - \theta_B)$-values at the various points. Thus, starting with Point A, $\frac{k_B}{k_B + k} = \frac{3.2}{3.2 + 2.5} = 0.562$; $\frac{3.2}{5.4} = 0.592$; $\frac{3.7}{5.9} = 0.627$, etc. Next, the $k(\theta_A - \theta_B)$-values are given which are equal to $0.562 \times 2.5 = 1.405$; $0.592 \times 2.2 = 1.302$; $0.627 \times 2.2 = 1.379$ etc., the total being equal to 10.40. The relative resistances were computed as shown on the next line in the table. Then the relative column resistances to the lateral load $P_{n+1} = 1$ were computed; and, in a similar manner, these values were computed using the lower floor beams, the results being 0.135; $0.126 + 0.132 = 0.258$; $0.199 + 0.223 = 0.422$; and, 0.185. Finally, using both floors as the author does, the corresponding values were: 0.135; $0.126 + 0.132 = 0.258$; $0.198 + 0.223 = 0.421$; and, 0.186. Table 2 (*a*) shows the comparison of these relative resistance values as obtained for each case and further compares them with the same values as obtained by the author. The disagreement between the writer's and author's values is probably due to the fact that Mr. Gottschalk has used the slide-rule. In order to make certain and to ascertain the probable percentage of error by comparing each case, all computations were extended at least three decimal places and in some instances even five places.

Table 2 (*a*) shows a close agreement in the first three columns, which would lead to the definite conclusion that the relative resistance values of columns may be obtained by taking into account either the upper floor beams, the lower floor beams, or the beams of both floors. It is interesting to compare the author's results with those of the writer as shown in Columns (3) and (4) of Table 2 (*a*) (since both have been developed under the same assumptions) in order to ascertain the probable error caused by the use of the slide-rule. Thus, at Column B $\frac{0.265}{0.258} = 1.027$; and, at $\frac{415}{421} = 98.6$; or, 2.7% at Column A and 1.4% at Column B. In other words, this comparison shows that the slide-rule may cause an error of as much as 3 per cent.

TABLE 2.—COMPARISON OF RESISTANCE VALUES OF BUILDING COLUMNS

Column	Case I, using the upper floor beams (1)	Case II, using the lower floor beams (2)	Case III, using both floors (3)	Gottschalk analysis (4)
	(*a*) FOR A LATERAL LOAD $P_{n+1} = 1$			
A	0.135	0.135	0.135	0.135
B	0.125 + 0.133 = 0.258	0.126 + 0.132 = 0.258	0.126 + 0.132 = 0.258	0.125 + 0.140 = 0.265
C	0.197 + 0.224 = 0.421	0.199 + 0.223 = 0.422	0.198 + 0.223 = 0.421	0.198 + 0.217 = 0.415
D	0.186	0.185	0.186	0.185
Total	1.000	1.000	1.000	1.000
	(*b*) FOR A LATERAL LOAD $P_n = 1$			
A	0.121	0.119	0.120	0.121
B	0.126 + 0.133 = 0.259	0.124 + 0.114 = 0.238	0.125 + 0.122 = 0.247	0.248
C	0.197 + 0.226 = 0.423	0.183 + 0.254 = 0.437	0.189 + 0.242 = 0.431	0.432
D	0.197	0.206	0.202	0.203
Total	1.00	1.00	1.00	1.00

Again referring to Table 1, the horizontal shears, T, in kips, were computed; and, since they are a direct function of the relative column resistances which are the same in all three cases, the results are: 3.9, 7.4, 12.1, and 5.4; and, if bending moments are computed with inflection points assumed at mid-height of columns, the corresponding values (in kip-feet) are: 27.3, 51.8, 84.7, and 37.8. In order to obtain the vertical reactions, the shears at the bays were computed as shown on the next to last line in Table 1. The last line, completing the table, gives the vertical reactions at the four columns of the structure.

In a similar manner, the writer computed the relative resistance values of building columns for the *n*th story, due to the lateral load $P_n = 1$ at the top, as shown in Fig. 2. These values were computed, first taking into account the upper floor beams only, as in Table 1. The same values utilizing the lower floor beams, and the beams of both upper and lower floors, were derived as in Table 1.

Table 2 (*b*) affords a comparison of the relative resistance values of columns as obtained in each case and also compares it with the values obtained by the author.

A comparison of values in Table 2 (*b*) (see Table 3) shows a maximum error of only 4.86% in the extreme case, which would again lead to the conclusion that the relative resistance values of columns may be obtained by taking into account either the upper floor beams or the lower floor beams or the beams of both floors.

TABLE 3.—Comparison of Percentage Errors in Relative Resistance Values

For column:	Cases I and II, Respectively, with Case III, Yield:			
	Case I		Case II	
	Computation	Percentage error	Computation	Percentage error
B	$\frac{12}{247} \times 100$	+ 4.86	$\frac{9}{247} \times 100$	− 3.65
C	$\frac{8}{431} \times 100$	− 1.86	$\frac{6}{431} \times 100$	+ 1.39
D	$\frac{5}{202} \times 100$	− 2.48	$\frac{4}{202} \times 100$	+ 1.98

Table 4 gives a comparison of the horizontal shears T, the moments M, and the vertical reactions R, for all columns of the structural bay, for each case, with the probable percentages of error. The maximum probable error in computations of bending moments and shears is only 5% and is sufficiently accurate for all practical purposes. The percentages for vertical reactions were neglected since the reactions are so small that an error of even 100% would not affect the design materially.

TABLE 4.—Comparison of Horizontal Shears, Bending Moments and Vertical Reactions

	Kips	Percentage error	Kips	Percentage error			Kip-feet	Percentage error	Kip-feet	Percentage error						
A	3.9	0.0	3.9	0.0	3.9	3.9	31.2	0.0	31.2	0.0	31.2	31.2	−7.6	−7.5	−7.5	−7.7
B	8.4	+5.0	7.7	−3.8	8.0	8.1	67.2	+5.0	61.6	−3.8	64.0	64.8	+0.0	+0.7	+0.3	+0.6
C	13.7	−2.1	14.1	+0.7	14.0	13.9	109.6	−2.1	112.8	+0.7	112.0	111.2	−0.2	−1.7	−1.0	−1.0
D	6.4	−0.2	6.7	+0.3	6.5	6.5	51.2	−0.2	53.6	+0.3	52.0	52.0	+7.8	+8.5	+8.2	+8.1

An attempt was also made to obtain similar values for the three cases for the ground floor, but since the columns at this point are assumed to be entirely fixed, it can readily be seen that in order to obtain the relative resistances, both ends of columns must be considered. However, the computations for the ground floor were tabulated as in the other cases, taking into consideration: (1) The upper beams only, (2) the lower end of columns only, and (3) both ends as solved by the author. The results (not included herein) showed sufficient disagreement to emphasize the necessity of ascertaining the condition of column fixity at both ends before analysis is made.

The beam shear method of obtaining the approximate shear, T, in beams and reactions, R, in columns, as outlined by Mr. Gottschalk, is rather ingenious. This method is relatively simple, and with little experience an analysis can be made in a relatively short time. The writer has checked the computations, extending them to a greater degree of accuracy and finds no serious discrepancies.

In conclusion, it may be added that the very simplicity and brevity of the theoretical analysis and derivation of formulas, as well as the ready applicability of the method to practical problems, are indeed a worthy contribution to such a highly controversial subject, and the author is to be congratulated for his effort to lighten the burden of engineers and designers engaged in this field of endeavor. Undoubtedly many short cuts will be found as familiarity with either the "column-shear" or "beam-shear" method is gained. Thus, since nearly the same relative resistance of the columns to unit lateral displacement was obtained for a given set of columns, in a particular bay, by utilizing the beams of the upper, lower, or both floors, it can be seen readily that intelligent application of the method will lead the experienced engineer to choose that set of k-values in the beam system which will result in simple computations, thereby saving considerable time and minimizing the chances of errors.

OTTO GOTTSCHALK,[18] ESQ. (by letter).—The discussions by Professor Carpenter and Mr. Winick are to be highly commended. Equation (8) will serve as a guide toward the proper dimensioning of structural parts to account for the final elastic action of the structure, especially for earthquake design; and Mr. Winick's suggestion that the analysis of stiffness of a story be based on either lower or upper beams only is a further great simplification and convenience, especially for preliminary and tentative studies. Both upper and lower beams must be considered when k-values are not proportional; for instance, in Fig. 3(a), when the k-values of the beams in the top floor (see Line 2) are 3.5, 4, and 6, and in the bottom floor (see Line 5) 12, 6, and 4 in.^{3}, the differences between results from either upper or lower beams are only about 30% and may create a wrong picture of the distribution and sign of stresses. The upper and lower floor beams must also be given equal weight when the joint stiffnesses given in Line 7 of Fig. 3(a) are to be used for the calculation of deflection and the period of oscillation of the skeleton.

A report of exceptional value, concerning the Empire State Building, in New York, N. Y., has been presented by J. Charles Rathbun, M. Am. Soc. C. E.,[19] and also in the discussions of this paper such as that by Colin Skinner, Assoc. M. Am. Soc. C. E.,[20] who present fundamental observations not previously available to the profession. In the writer's opinion, no work on the subject of wind bracing can claim to be complete in the future without referring to that paper. It certainly proves the need for some simplified method of wind-stress analysis such as the one presented by the writer.

[19] "Wind Forces on a Tall Building," by J. Charles Rathbun, *Proceedings*, Am. Soc. C. E., September, 1938, p. 1335, and December, 1939, p. 1771.

[20] *Loc. cit.*, June, 1939, p. 1024.

Even in the greatest of buildings the distribution of the many varieties of material cannot be expected to be perfect at the beginning of its life. Nature must work with irresistible force to bring about that perfection after, say, ten or fifteen years, so that finally every kind of material will work as a part of the structure, in harmony with its physical properties. Thus, one more new and interesting responsibility rests upon the engineer to design and balance the resisting structure so that the building may be perfect as soon as possible after its completion. He must provide appropriate joints in the masonry work, from the first, in such a way as to assure its permanent co-operation in the maintenance of joint stiffness.

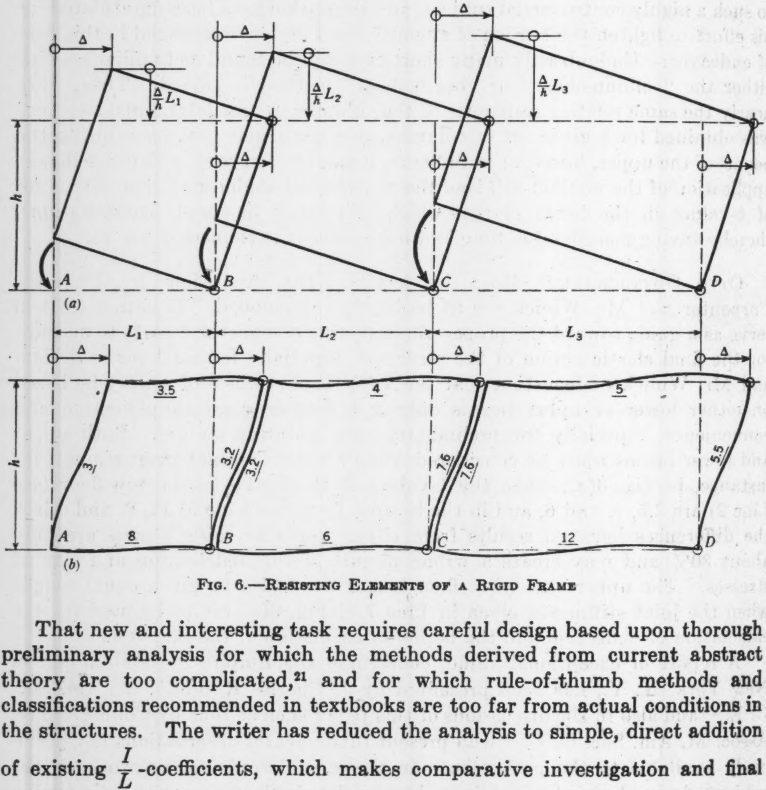

FIG. 6.—RESISTING ELEMENTS OF A RIGID FRAME

That new and interesting task requires careful design based upon thorough preliminary analysis for which the methods derived from current abstract theory are too complicated,[21] and for which rule-of-thumb methods and classifications recommended in textbooks are too far from actual conditions in the structures. The writer has reduced the analysis to simple, direct addition of existing $\frac{I}{L}$-coefficients, which makes comparative investigation and final design easy, rapid, and interesting. Incidentally, the method presented affords a better distribution and a considerable economy of steel.

Fundamental Conceptions.—As stated in the "Synopsis," the analysis presented is an application of the natural geometrical conception[3] based upon model statics.[2] Although the experimental or geometrical method of analysis simplifies, equally, all other comparatively intricate statical problems, the analysis of wind stresses is possibly one of the fields most in need of perfecting, and therefore it has been emphasized in the paper.

---

[21] "Wind Bracing in Steel Buildings," Sixth Progress Report of Sub-Committee No. 31, Committee on Steel of the Structural Division, *Proceedings*, Am. Soc. C. E., June, 1939, p. 969.

In principle, it should be remembered that, whereas the methods based on current abstract statics tend to anticipate complications over the entire structure, in the way of redundants, etc., the experiments and theory derived from the writer's method consider and deform only the stressed element that is to be analyzed and take into account only those of the surrounding structural members which are visibly affected by that deformation. When it seems necessary to refine the results, appropriate corrections are applied rather than recomputations that complicate the procedure fundamentally. In wind-stress analysis, moreover, the complications of "exact" methods are the less justified because an unknown part of the stresses, estimated as between one-half and nine-tenths, is being absorbed by brick work.

The theory explained in the paper may be further illustrated by reference to Fig. 6. A floor of the structure shown in Fig. 3(*a*) may be assumed to consist of three resisting elements or independent frames formed by the columns and beams of the three bays. First rotate each frame about Points *B*, *C*, and *D* (Fig. 6(*a*)) through an angle $\tan^{-1} \dfrac{\Delta}{h}$; fix each joint against rotation between the adjacent members meeting at that joint; and restore the vertical displacement of the two joints that were elevated in the first step. The resultant deformation is shown diagrammatically in Fig. 6(*b*).

The conclusions of the Committee on Wind Bracing[21] confirm the results of the writer's investigations. One of the conclusions may be quoted as a welcome, progressive step: "The wind-reaction ratio—that is, the ratio of vertical wind reaction of inner column to that of outer column—was seen to be wholly determined by the relative sizes of members and to be entirely under control by properly varying these relative sizes."[22] This conclusion is the more valuable because the Committee arrived at the same results along entirely different lines of approach. At the same time, the report emphasizes the necessity of an analysis, such as the one presented herein, which may be applied quickly and easily to frames of any number and length of bays. The writer has applied the simplified analysis to all beams and columns of the interesting three-bay, ten-story bent of the University of Pennsylvania tests, the bending moments of which were given in the report. His analysis showed a close agreement with those obtained by the Cross method—within 0 to 2% in most cases and as much as 5% in a few exceptional cases. The same stiffness values calculated for the bending moments served to obtain the comparative deflection immediately.

Tentative Designs.—As an example of an unsymmetrical frame of six bays, consider Fig. 7. In Fig. 7(*a*) the four central spans are long in relation to the two exterior spans; in Fig. 7(*b*) they are short in the center but long at the ends; and in Fig. 7(*c*) the three left spans are long and the remaining ones are

(*c*) SPANS LONG AT ONE END

FIG. 7.—TYPICAL COLUMN SHEAR AND REACTIONS IN SIX-BAY FRAME FOR DIFFERENT COLUMN SPACINGS

short. To obtain a uniform criterion the k-values of beams in the three designs have been assumed to vary in relation to spans and the k-values of the columns in relation to half the lengths of adjoining bays. The total floor loading has been assumed at 150 lb per sq ft and the load of exterior walls at 1 kip per front ft of each story. Under each of the three arrangements in Fig. 7 there is a diagram of column shear and one of the column reactions, with the shears in the beams indicated in parentheses.

These diagrams are most instructive and their convenience can scarcely be over-estimated. Wide spacing of end spans (see Fig. 7(*b*)) make the reactions approach a planar distribution, whereas short exterior spans, such as in Fig. 7(*a*), produce the most marked differences between the reactions of exterior and the nearest interior column. This would agree with Mr. Skinner's observation:[23] "Cracks were also observed in the concrete floors at the first row of interior columns, parallel to the exterior walls." Consequently, where diagrams of reactions, such as those of Fig. 7, indicate abrupt differences between reactions at exterior spans and where prevention of cracks is considered important, joints or dummy joints are advisable at the first row of columns unless, in the architectural design, exterior spans may be widened until the reaction diagram (Fig. 7) shows a more planar distribution, although the cost of the steel frame may be higher.

Note that at reactions of the two exterior columns at each side of the structures a slight correction may be applied, as shown at the end of the paper.

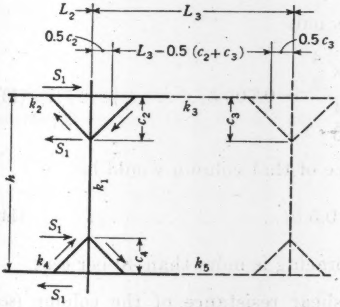

FIG. 8.—WIND BRACING

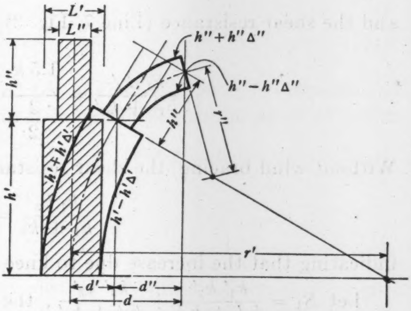

FIG. 9.—DEFLECTION OF BENT FROM UNIFORM CHANGE OF LENGTH OF EXTERIOR COLUMNS

Wind Bracing.—Knee bracing at the ends of columns has the effect of shortening the free length of both columns and beams, thus increasing the stiffness values from k to k'. For conditions shown in Fig. 8, the k'-values may be computed as follows:

$$k_1' = \frac{h\,k_1}{h - b_2 - b_4} \dots\dots\dots\dots\dots\dots (9)$$

in which

$$b_2 = c_2\,\frac{k_2 + k_3}{k_1 + k_2 + k_3} \dots\dots\dots\dots\dots\dots (10a)$$

---

[23] *Proceedings*, Am. Soc. C. E., June, 1939, p. 1025.

and

$$b_4 = c_4 \frac{k_4 + k_5}{k_1 + k_4 + k_5} \ldots\ldots\ldots\ldots\ldots\ldots (10b)$$

Furthermore,

$$k_2' = \frac{L_2\, k_2}{L_2 - 0.5\,(c_1 + c_2)} \ldots\ldots\ldots\ldots\ldots\ldots (11a)$$

and

$$k_3' = \frac{L_3\, k_3}{L_3 - 0.5\,(c_2 + c_3)} \ldots\ldots\ldots\ldots\ldots\ldots (11b)$$

Then, the stiffness quotients corresponding to Line 2, Fig. 3, are $\frac{k_2'}{k_1' + k_2'}$ and $\frac{k_3'}{k_1' + k_3'}$, making the shear resistance of column (Line 7, Fig. 3) $\frac{k_1'\, k_2'}{k_1' + k_2'}$ and $\frac{k_1'\, k_3'}{k_1' + k_3'}$.

For example, let $k_1 = k_2 = k_3 = k_4 = k_5$; $c_2 = c_3 = c_4 = 0.25\,h$; and $L_3 = h$. Then $b_2 = 0.25\,h \times \frac{2}{3} = \frac{h}{6} = b_3$; and

$$k_1' = \frac{k_1}{1 - \frac{1}{3}} = 1.5\,k_1 \ldots\ldots\ldots\ldots\ldots\ldots (12a)$$

and

$$k_3' = \frac{k_3}{1 - 0.25} = 1.33\,k_3 \ldots\ldots\ldots\ldots\ldots\ldots (12b)$$

and the shear resistance (Line 7, Fig. 3) equals

$$\frac{k_1'\, k_3'}{k_1' + k_3'} = \frac{1.5\,k_1 \times \frac{4}{3}}{\frac{3}{2} + \frac{4}{3}} = 0.706\,k_1 \ldots\ldots\ldots\ldots\ldots (13)$$

Without wind bracing, the shear resistance of that column would be:

$$\frac{k_1\, k_3}{k_1 + k_3} = 0.5\,k_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

indicating that the increase due to knee bracing is more than 40 per cent.

Let $S_1 = \frac{k_1'\, k_2'}{k_2' + k_3'} + \frac{k_1'\, k_3'}{k_2' + k_3'}$, the shear resistance of the column (see Fig. 8); then the 45° knee bracing will receive a stress at the upper left and right sides, respectively, of $\frac{1.4\, S_1\, k_2}{k_2 + k_3}$ and $\frac{1.4\, S_1\, k_3}{k_2 + k_3}$. In steel structures the heights c_2 and c_4 of the knee bracing should be measured from the outside rivets, and in reinforced concrete structures from the most remote steel bars crossing the column.

Deflection from Wind Stresses.—A further interesting application of the simplified analysis is the calculation of deflection or sway of tall buildings by means of the shear resistance at the floors (shown at Line 7, Fig. 3), applying the actual values of $k = \frac{I}{L}$ in beams and $k = \frac{I}{h}$ in columns.

The total deflection of a structure may be analyzed as the sum of three distinct stress actions which, in the inverse order of their numerical importance, are as follows:

1. Direct Shear at Columns.—The direct shear at columns, due to wind pressure, without discounting the large portion actually absorbed by the walls, will generally not exceed 0.26 kips for every square inch of steel section of columns. For the steel, the modulus of elasticity in shear is assumed at $E_s = 13\,000$ kips per sq in. The deflection from direct shear will not exceed 0.24 in. for every 1 000 ft of height of the building and therefore, generally, may be neglected.

2. Reactions in Exterior Columns.—The pull at the left and the compression at the right exterior columns, resulting from reaction diagrams as shown in Fig. 7, lengthens the first and shortens the latter. A prism of width L' and height h' (Fig. 9), one side of which is uniformly lengthened by Δ' and the opposite side shortened by Δ' per unit of length, forms a circular arch of radius r', such that: $\dfrac{r' + \dfrac{L'}{2}}{r' - \dfrac{L'}{2}} = \dfrac{h' + h'\,\Delta'}{h' - h'\,\Delta'}$; and

$$r' = \frac{L'}{2\,\Delta'} \ldots\ldots\ldots\ldots (15)$$

At the height of h' the "geometrical" deflection d' (see Fig. 9) is $(r' - d')^2 = (r')^2 - (h')^2$; or

$$d' = \frac{(h')^2}{2\,r'} = \frac{(h')^2\,\Delta'}{L'} \ldots\ldots\ldots\ldots (16)$$

A prism of base L'' and height h'' on top of the base prism, lengthened and shortened respectively by Δ'' per unit of height, will form a curve of radius $r'' = \dfrac{L''}{2\,\Delta''}$ and deflect $\dfrac{(h'')^2\,\Delta''}{L''} + \dfrac{2\,h'\,h''\,\Delta'}{r'}$, so that the total deflection d'' on top of the upper prism is:

$$d'' = \frac{h'\,\Delta'\,(h' + 2\,h'')}{L'} + \frac{(h'')^2\,\Delta''}{L''} \ldots\ldots\ldots\ldots (17)$$

Equations (15), (16), and (17) apply also for any other difference of height, $2\,h'\,\Delta'$ and $2\,h''\,\Delta''$, caused by uniform extension or compression of both exterior columns, or in one column only with respect to the other—as, for instance, from change of temperature along one side of the building.

In the field it is not likely that exterior columns will be required to sustain an average wind stress over their total length of more than 2 kips per sq in.; assuming $E = 30\,000$ kips per sq in. (see Fig. 9), this would make $\Delta' = \Delta'' = \dfrac{2}{30\,000} = \dfrac{1}{15\,000}$. As an example, let: $h' = 400$ ft, $L' = 200$ ft, $h'' = 200$ ft, and $L'' = 100$ ft, making $h'\,\Delta' = \dfrac{4}{150}$ ft and $h''\,\Delta'' = \dfrac{2}{150}$ ft. Then, by Equation (16), $d' = \dfrac{4 \times 400}{200 \times 150} = 0.0533$ ft; by Equation (17), $d'' = \dfrac{2 \times 200}{100 \times 150}$

$+ \frac{2 \times 4 \times 200}{200 \times 150} = 0.0800$ ft; and (see Fig. 9) $d = d' + d'' = 0.1333$ ft $= 1.6$ in. This displacement may be termed a geometrical effect of uniform alteration at exterior columns.

3. Aggregate Sway of Floors.—Referring to Fig. 1, Equation (5), for $\Delta \leqq 1$, may be written as follows:

$$P = \frac{6\,E\,k\,(\theta\,\Delta - \theta'\,\Delta)}{h^2} \quad \text{.....................(18)}$$

If the deflection of any one story of height, h, being $\theta = \frac{f'}{h}$ and $\theta' = \frac{f}{h}$:

$$\Delta = \frac{P\,h^2}{6\,E\,[\Sigma k\,(\theta - \theta')]} \quad \text{.....................(19)}$$

For example, at the *n*th floor of the frame in Fig. 3, according to Line 7: $\Sigma k\,(\theta - \theta') = 31.67$ in.³ Furthermore: $P = 32.4$ kips; $6\,E = 180\,000$ kips per sq in.; $h = 16 \times 12 = 192$ in.; and $d = \frac{32.4 \times 192^2}{31.67 \times 180\,000} = 0.2095$ in. In other words, the deflection is $\frac{100 \times 0.2095}{16} = 1.31$ in. per 100-ft height of building. However, if the height of the floors was only 12 ft, the horizontal deflection would be only 0.72 in. per 100 ft. Although Equation (19) does not take into account the reciprocal influences of stiffness and displacements between floors, experience indicates that it presents a sound basis for calculating deflections. After more observations on existing buildings become available, it may possibly be completely corroborated.

In Fig. 10 an analysis of this part of the deflection of a structure has been illustrated. One bent only has been shown as an example. In practical application, however, all bents joined by rigid floors must be assumed to resist, jointly, the total wind pressure upon the building, taking into account possible effects of eccentricity of the wind force. Walls anchored within a bent will be treated separately.

Walls in Skeleton.—Walls tied to columns within a bent increase the rigidity and reduce the deflection of that bent. The simplified wind-stress analysis may be applied to analyze and judge the possibilities and limitations of that ever-present structural element.

A 25-story bent with a distribution of bays similar to Fig. 7(*b*) but with a rigid wall joining Columns *B* and *C*, as would be required for an elevator shaft or staircase, has been illustrated in Fig. 10. It is assumed that cross braces or some other form of reinforcement tie the wall firmly to Columns *B* and *C* (at least in the lower floors) so that these columns act as chords of a vertical cantilever beam fixed at the ground floor. At the same time Columns *B* and *C* act, at all the floors, as members of the frame, the same as all other columns, and they contribute to the joint wind force a resistance, $\Sigma k\,(\theta - \theta')$, at the several floors, as analyzed in Line 7 of Fig. 3.

This joint resistance may be called the "section modulus" of the bent or frame at the several floors, in the same sense as $\frac{I}{c}$ is defined as the section

FIG. 10.—DIAGRAMS OF "SECTION MODULUS" AND DEFLECTION FOR A TWENTY-FIVE STORY BENT WITH A "WALL" BAY

modulus of an ordinary beam; and, like $\frac{I}{c}$, its dimension is in inches³. In Fig. 10 the wind pressure has been assumed to be 20 lb per sq in., distributed over the entire height of the bent so that the aggregate shear increases uniformly from 0 at the top to $w = 97.92$ kips on the bottom, as shown by the solid line at the right. Similarly, the section modulus converges from a maximum at the bottom of the structure to a minimum at one of the upper floors where only vertical loads are considered. This is shown as a dashed line in the shaded area to the right of the frame in Fig. 10. It is a valuable guide and check for rational proportioning at intermediate floors. At the upper part of that diagram it is interesting to note that, beams being equal in the several floors, the "section modulus" increases only about 20%, which represents the increase of $k = \frac{I}{h}$ in the columns.

Similarly, the deflection derived from total sway at floors of equal height increases uniformly from the bottom to the top as indicated by Curve (*c*), Fig. 10, and need be calculated at a few floors and at the top only. From the second to twenty-fifth floor (Fig. 10) the story height is uniformly 12 ft so that Equation (19) becomes $\frac{h^2}{6\,E} = \frac{144^2}{6 \times 30\,000} = 0.1152$; and $\Delta = \frac{0.1152\,P}{\Sigma k\,(\theta - \theta')}$.

Curve (*c*), Fig. 10, has been drawn, assuming that the frame supports all of the wind load, without considering the resistance and the wall *B C*. In the bottom floors, Columns *B* and *C* (which form the chords of the cantilevered wall) have areas of 69 and 45 in.² and moments of inertia of 5 100 and 2 100 in.⁴, respectively; and they are 17 ft (or 204 in.) apart. The moment of inertia of the wall, therefore, is: $I = 5\,100 + 2\,100 + \frac{69 \times 45 \times 204^2}{69 + 45} = 114.06 \times 10^4$ in.⁴ and $E\,I = 342.18 \times 10^8$ kip-in.²

The wall alone, as a free cantilever 306 ft (or 3 672 in.) long, loaded uniformly by $16 \times \frac{0.02}{12} = 0.0267$ kip per in. deflects as shown by Curve (*e*), Fig. 10, and would neither contribute to stiffness nor reduce deflection. However, since Columns *B* and *C* are part of the frame, one may assume that the wall *B C* acts as a cantilever fixed at the bottom and loaded at the several floors. The shear decreases uniformly from 97.92 kips at the bottom to 0 at some level, distant x above the ground, so that at $\frac{x}{2}$ the deflection of the cantilever would be equal to the sway of the skeleton without the wall *B C*.

TABLE 5.—ANALYSIS TO DETERMINE THE DEFLECTION OF A TWENTY-FIVE-STORY BENT (SEE FIGURE 10)

Floor (1)	External load, P, in kips (2)	$\Sigma k(\theta - \theta')$, in inches³ (3)	Deflection Δ, in inches per 12 ft of height (4)	Number of stories included in section (5)	Deflection Δ, in inches per section (6)	Total deflection, in inches (7)

FIG. 11.—DEFLECTION CURVES OF CANTILEVER BEAMS FOR (a) UNIFORM LOAD, AND (b) AND (c) TRIANGULAR LOADS

Substituting, for the pressures at the several floors, a distributed load which varies uniformly from $\frac{97.92}{144} = 0.68$ kip per in. at the bottom to 0 at a distance x, the value of x (Fig. 10) can be obtained from the following equation (see Fig. 11(b)):

$$0.383 \times 0.68 \times \frac{x^4}{30\,E\,I} = 3.347 \times 10^{-4}\,x \ldots\ldots\ldots\ldots (20)$$

Therefore, $x^3 = 1.31924 \times 10^9 = 1\,096.8$ in. $= 91.4$ ft—that is, approximately 92 ft. The deflection at $\frac{x}{2}$ is $d = 46.0 \times 12 \times 3.347 \times 10^{-4} = 0.1848$ in. and therefore the reduced deflection of the bent, due to the wall, is $0.5\,d = 0.0924$ in.

The bending moment of the wall, at the bottom (see Fig. 10), is $M_0 = 2.13 \times 90 + 14.9 \times 78 + 27.7 \times 66 + 40.45 \times 54 + 53.22 \times 42 + 65.99 \times 30 + 78.76 \times 18 = 10\,999.00$ kip-ft, and therefore the additional reaction at Columns B and C to be resisted is $\pm \frac{10\,999.00}{17} = \pm 647$ kips.

On the other hand, the section modulus at the floors below x may remain constant, thus saving the additional steel in beams which the increase of "section modulus," according to the shaded area in Fig. 10, would require without the wall action.

Cantilever walls may start at the ground floor or at any upper floor at which fixation is assured by three horizontally rigid floors capable of transmitting the fixing stresses to other rigid walls below. This facilitates the design of offsets in walls without lessening the wind stiffness of the structure and may also be of temporary value to make up for local lack of rigidity, especially during construction and before the exterior walls have been placed in all of the floors.

To produce the "wall effect" the "wall" need not be resistant and rigid in itself. Cross braces, reinforced continuous plaster, etc., may also be designed to produce the "wall" action. A rigid panel within each of the flexible stories, one on top of the other, is certain to absorb a disproportionate part of the wind shear of every floor and, as shown by Figs. 3 and 6, to throw excessive reactions to Columns B and C, producing deformations and cracks as stresses accumulate, especially toward the lower floors of the building. This action has been confirmed by competent observation:[24] "There were relatively few cracks in the plastered ceilings; but the plastered partitions surrounding the elevator shafts were seriously cracked in the lower portion of the main tower and cracked to a lesser degree in the upper stories."

Inconveniences of that type are quite common around shafts or staircases of buildings of even moderate height, and prove the necessity for studying, in every case, the merits of utilizing or discontinuing the wall effect. The example illustrated in Fig. 10 shows that phenomenon and demonstrates how excessive sway at the top of a tall building may be reduced by reinforcement at the bottom, although at considerable expense.

Bending Lines of Cantilevers.—For possible combinations of cantilever walls the following data referring to a beam $A\,B$ of constant section, fixed at Point A (Fig. 11), will be of interest. When the moment of inertia I is decreasing uniformly from the bottom (A) to the top (B), it may be taken as the I-value at about $x = \frac{h}{4}$ above the bottom. A fairly close approximation is obtained by substituting tangents to the curves at Points A and B'. The last three lines of Table 6 are based on that assumption, with $y = 0$ for the lower heights, $\frac{h}{4}$, $\frac{h}{5}$, and $\frac{4\,h}{15}$, respectively.

Earthquake Stresses.—In territories subject to earthquake shocks, it now seems customary to specify, for the statical computation, a horizontal force at each floor equal to one-tenth of the overlying vertical load. This will make the horizontal force in normal buildings six to twelve times the usual wind pressure, and the additional shears and reactions will become really important even for low buildings; and the simplified analysis will be so much more necessary. The following definition by Mr. Jacob J. Creskoff[25] may be quoted:

> "The seismic force, $F = W\,K$, acts against the mass of a building. Assuming that the mass is concentrated at the floor levels, and that floors are horizontal girders that deflect as units, then the columns and beams between two consecutive floors may be regarded as vertical beams—deflecting equally because of a concentrated horizontal force acting against the upper floor—and with end fixities determined by the degree of fixity between the vertical beams and the floors. Under these assumptions, the seismic force is distributed to all of the vertical beams, and to each in proportion to its relative rigidity."

To take care of these elementary forces, the simplified wind-stress analysis will apply directly, especially Equation (8); beyond that it will facilitate the distribution of columns along the lines suggested in Fig. 7 and contribute to the formation of a resisting nucleus within the structure to cope best with the effects of oscillation.[26]

Stresses in Existing Buildings.—The simplified wind-stress analysis may be used to advantage in determining stresses of skeletons in existing buildings, the investigation of which should be stimulated to arrive at a better knowledge of the permanent stiffness conditions of structures and of the portion of stresses definitely absorbed by masonry work.[27]

Unless perfect measuring and recording instruments are available in abundance, it is convenient,[27] and economical, to place small, flat, metal boxes in the base layer of existing floors, next to the columns, so that they follow safely the vertical oscillations of the latter. The boxes should be sealed hermetically and should contain an easy flowing liquid. Two boxes communicate by means of small rubber or metal tubes placed out of the way along partitions, etc. The slightest lifting of one of the boxes will cause at the communicating box an overflow into an attached receptacle, or glass tube, which may be weighed, measured, or read annually or semi-annually; the sum of the overflow of each pair of boxes indicates the maximum change in level between the two respective columns. If the boxes are $2\frac{1}{2}$ in. by 4 in. by 8 in., every 0.01 in. change of level shows a column of liquid 6.52 in. long in a $\frac{1}{4}$-in. glass tube, so that even $\frac{1}{1\,000}$ in. can be estimated.

---

[26] *Proceedings*, Am. Soc. C. E., December, 1938, p. 1993.

[27] "Wind Forces on a Tall Building," by J. Charles Rathbun; discussion by Otto Gottschalk, *loc. cit.*, May, 1939, p. 880.

It will be advisable, if possible, to set a series of pairs of boxes at two or three different floors in tall buildings; and, at one or two floors below or above each series, one pair should be set at each of the exterior panels (see Fig. 12). Assuming a story height of 12 ft, a change of level of 0.01 in. between two floors represents an additional column pressure of 2 kips per sq in. of column section.

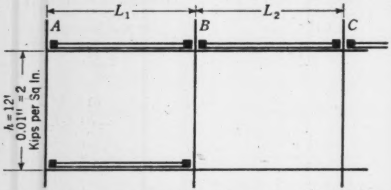

FIG. 12.—ARRANGEMENT OF BOXES FOR RECORDING RECIPROCAL CHANGES OF LEVEL AT COLUMNS

For example, consider the floor in Fig. 7(*c*) to be subjected to a total wind moment of 7 600 kip-ft. The first step is to analyze the frame according to Fig. 3, obtaining the diagram of reactions shown in Fig. 7(*c*). This supplies the sign of column pressures and, after some practice, permits the designer to estimate the reactions of most of the interior columns, thus simplifying readings at the building. Suppose the readings are as follows, in kips: $AB = -42.2$; $BC = -17.9$; $CD = +13.2$; $DE = -12.3$; $EF = +10.7$; and $FG = -81.6$. The seven unknown column reactions $A, B, \cdots G$ are calculated as follows:

$$\begin{array}{lr}
 & \text{Kips} \\
A - B \qquad\qquad\qquad\qquad = & -\ 42.2 \\
A - C = -42.2 - 17.9 = & -\ 60.1 \\
A - D = -60.1 + 13.2 = & -\ 46.9 \\
A - E = -46.9 - 12.3 = & -\ 59.2 \\
A - F = -59.2 + 10.7 = & -\ 48.5 \\
A - G = -48.5 - 81.6 = & -130.1 \\
A+B+C+D+E+F+G = & 0.0 \\
\hline
7A \qquad\qquad\qquad\qquad\qquad = & -387.0
\end{array}
\qquad
\begin{array}{lr}
 & \text{Kips} \\
B = 42.2 - 55.3 = & -13.1 \\
C = 60.1 - 55.3 = & +\ 4.8 \\
D = 46.9 - 55.3 = & -\ 8.4 \\
E = 59.2 - 55.3 = & +\ 3.9 \\
F = 48.5 - 55.3 = & -\ 6.8 \\
G = 130.1 - 55.3 = & +74.8 \\
A = -387.0 \div 7 = & -53.3 \\
\hline
A+B+C+D+E+F+G = & 0.0
\end{array}$$

Inverting the process illustrated in Fig. 3(*a*), one may obtain from those column reactions all other stresses of columns and beams of the structure which are desired. The differences between reactions analyzed and recorded will indicate the proportion absorbed by masonry work.

In conclusion the writer hopes that he has shown an efficient method of analyzing wind stresses in tall buildings. Since the inherited abstract conception of structural statics has failed to provide engineers with adequate methods of analysis in this field of design as well as in others, it must be replaced by more natural devices and lines of reasoning. Apparently, skyscrapers are neither uneconomical nor harmful to street traffic,[28] and the engineer can contribute much to encourage that most interesting field of technical activity. By wise distribution of materials the proper analysis of the steel frame will insure against annoying vibrations and unsightly deteriorations, and at the same time reduce the cost.

DESIGN OF A HIGH-HEAD SIPHON SPILLWAY

By Elmer Rock,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. J. C. Stevens, B. E. Torpen, G. E. Hyde, and R. B. Cochrane, I. M. Nelidov, and Elmer Rock.

Synopsis

A direct and clear-cut method of analysis, for use in determining the proportions of a high-head siphon spillway, is presented in this paper. The manner in which well-established principles of hydraulics are applied is outlined, general equations for the determination of throat area and outlet area are derived, and the application of the method as presented is illustrated by the solution of a specific problem.

Introduction

The siphon spillway has become increasingly popular as a device for the automatic control of water-surface elevations. In reservoirs maintained for recreational purposes, in canals, in head-water bays of hydro-electric power plants or, in general, wherever close regulation of pool elevation is necessary, such a device can be used to distinct advantage. Numerous installations in the United States and elsewhere have proved their practicability and adaptability, and they indicate that the siphon spillway occupies a definite place among worthy hydraulic structures.

This paper applies, in the main, to problems arising in connection with the determination of the proportions of a high-head siphon spillway. The term "high-head siphon" is used by the writer to denote siphons that operate under heads in excess of 34 ft, or the barometric height. The head in this case is the difference in elevation of the head-water and tail-water surfaces, or, if the outlet discharges into atmosphere, it is the difference in elevation of the head-water surface and the outlet. Siphons operating under heads less than 34 feet are termed "low-head siphons." The barometric height in feet of water represents the magnitude of atmospheric pressure and is of paramount importance when the action of high-head siphons is considered. The manner

---

Note.—Published in April, 1939, *Proceedings*.

[1] Hydr. Engr., U. S. Engr. Dept., U. S. Engr. Office, Providence, R. I.

in which its value enters into design computations and the effect it has upon siphonic action will be treated subsequently herein.

Strictly, the head at which a siphon becomes a high-head siphon should include some mention of head losses within the siphon tube as well as practical limitations on working pressures. For example, let it be assumed that the total available head at a site is 32 ft, the head lost in the entire structure is 6 ft, and the allowable negative pressure is 24 ft of water This would be a high-head siphon because there is an excess of head (2 ft) over and above the amount it is possible to utilize for producing flow. Cognizance of this excess head comprises one of the special considerations dealt with in this paper. The evaluation of head losses and the selection of an allowable negative pressure are given further mention in a later paragraph. It is believed that, because of its common usage and its vital significance, 34 ft serves, appropriately, to designate the dividing line between a high-head and a low-head siphon. Many of the principles contained in this paper may be applied to low-head siphons with equal effectiveness. The conditions dealt with in the design of low-head siphons, however, present separate problems of a different nature and no attempt will be made to include siphons in that classification.

In the past there has been some discussion concerning the feasibility and the performance of high-head siphon spillways. In general, it is now definitely established that heads far in excess of 34 ft may be utilized, and the action of spillways designed to function under such heads can be predicted with a reasonable degree of accuracy. It is probable that, in some cases, the tendency to over-design a siphon spillway is present. In other words, a factor of ignorance is included to offset the lack of a dependable basis for design. This is true because access to a definite rational method of analysis, carried through from beginning to end, and pertaining to the case at hand, is difficult to find in American literature. A review of the published articles dealing directly with this subject will reveal that methods presented are generally indirect and clumsy.

Some methods are based on the formula

$$Q = C\,A\,\sqrt{2\,g\,H} \quad \text{.......................} \quad (1)$$

in which: Q = the discharge; C = a coefficient of flow; A = area of cross-section; g = acceleration due to gravity; and, H = total hydraulic head available. Experiments and prototype measurement generally establish the value of C between 50 and 80 per cent. Equation (1) serves well to establish a basis for comparison of siphon spillways. It is inadequate for design purposes, however. In any case, it necessitates a cut-and-try procedure and does not take into account local conditions at critical sections. Particularly in the design of high-head siphons, it is inadequate in that no provision is made to convert the excess head into some form of energy such as heat or kinetic energy. The writer proposes to show how excess head is of utmost importance, and how it is provided for by proper dimensioning of the lower leg. In view of these shortcomings it may be said that, as it stands, Equation (1) does not represent a direct and thorough approach. Methods based on a study of the hydraulic gradient alone fail to take into account the nature of the flow in the upper bend where velocity distribution is entirely different from that in a straight pipe. The velocities used in the computation of this gradient are mean values and the pressures at the throat section, as measured from the gradient, do not represent actual localized pressure intensities. The writer does not wish to minimize the value of a plot showing the hydraulic gradient; certainly, it can be used to a great advantage, but its limitations must be recognized.

UPPER BEND AND THROAT

At the outset it must be understood that when a siphon is operating under a head greater than 34 ft, the excess head cannot be used to increase flow through the spillway. If two siphons were constructed, each having the same throat area and designed for maximum discharge, one operating under a 34-ft head and the other operating under an 80 ft head, the latter would not have a greater capacity. This fact is easily understood when the fundamental principle of siphonic action is considered. The lower leg of a siphon makes possible the existence of extremely low absolute pressures in the upper bend, but the only force being exerted to produce flow is the pressure of atmosphere on the head-water surface. Obviously the magnitude of this force is the limitation imposed by nature on all siphons.

Generally, the critical section of any siphon is at the crest. At this section the negative pressures are of greater intensity than at any other section in the siphon tube. Hence it may be concluded that the dimensional characteristics of the structure at its summit determine its capacity. In design work, therefore, it is only natural for initial studies to be confined to the throat of the siphon.

The upper bend is usually formed with regular curves of moderate radii. Almost always the tube is rectangular in cross-section at the summit. The manner in which the water flows—that is, its velocity distribution when passing through this portion of the siphon tube—is the basis for determining the size of the throat opening. The most recent experimental data show conclusively that when water flows through a bend in a conduit the velocity distribution is not symmetrical about the axis of the conduit cross-section. Furthermore, they indicate that velocities are greatest at the inside of the bend and decrease in magnitude toward the outside of the bend. The condition of flow is comparable to that in a free vortex. In the case of a siphon where the upper bend is a rectangular conduit it may be said that, for all practical purposes, the condition is analogous to free vortex flow. It is possible then to utilize the laws governing vortex action in the design of the throat section.[3]

Before any determination of proportions can proceed it is necessary to adopt a minimum absolute pressure that can be tolerated in practice. Theoretically, a high-head siphon could be designed to develop a vacuum of 34 ft of water at its summit, and this would represent the greatest possible efficiency. In other words the absolute pressure would be zero, or the lower theoretical limit. In practice, such degree of rarefaction can never be attained; vapor pressure and elevation above sea level decrease this figure appreciably. Water in its natural state has air in solution and, as the absolute pressure decreases, the quantity of air drawn from the solution increases. In the case of the siphon, this action may cause sufficient air to collect at the summit to interrupt the flow. Furthermore, with negative pressures approaching 34 ft of water, it would not be unreasonable to expect parting of the water from the crest, with its accompanying vibration and cavitation. As a general rule experience with siphon spillways has established 24 ft of water as a maximum negative pressure to be allowed at any point in the structure.[3] In other words the absolute pressure should not be permitted to be reduced below 10 ft of water.

---

[3] "Siphon Spillways," by A. H. Naylor, published in London, England, 1935, by Edward Arnold.

Frequently many of the dimensional characteristics of a siphon spillway are fixed by physical limitations of the structure in which it is incorporated. Thus the radii of curves which form the upper bend may not be dictated by consideration of hydraulic performance. If such limitation does not exist, then two general rules may be applied: (1) As the radius of curvature is increased the cross-sectional area to be provided at the throat decreases; hence it is obvious that excessively sharp curves should be avoided (the logic in this statement is demonstrated subsequently herein); and (2) as the radius of curvature decreases the priming qualities are enhanced. Thus to forestall difficulties from objectionable priming action it is desirable to avoid unduly large radii.

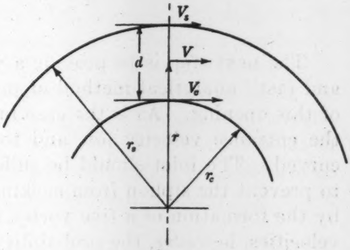

FIG. 1

Having thus fixed the minimum permissible absolute pressure and the upper bend radii, which tie in the depth of the throat section, it is possible to determine the discharge per foot of spillway crest. The maximum head to be utilized for producing velocity is 24 ft. Then the velocity in the upper bend cannot exceed $\sqrt{2\,g\,H} = \sqrt{2 \times 32.2 \times 24} = 39.3$ ft per sec. Referring to Fig. (1), the following procedure is established:

In free vortex flow. . . . . $V \times r =$ constant

Hence. . . . . $V \times r = V_c \times r_c \qquad = V_s \times r_s$

Or. . . . . $V \qquad = \frac{V_c\,r_c}{r}$

From the foregoing computation. . . . $V_c \qquad = 39.3$ ft per sec

Then. . . . . $V \qquad = \frac{39.3\,r_c}{r}$

The discharge for a small element of depth dr is

$$dQ_1 = V\,dr \qquad (2)$$

Substituting for V

$$dQ_1 = \frac{39.3\,r_c}{r}\,dr \qquad (3)$$

---

[3] *Proceedings*, Inst. C. E., Vol. 231 (1930–31), p. 201.

Integrating between the limits of r_c and r_s

$$Q_1 = 39.3\, r_c \int_{r_c}^{r_s} \frac{1}{r}\, dr = 39.3\, r_c \log_e \frac{r_s}{r_c} \quad \ldots\ldots\ldots\ldots\ldots (4)$$

Equation (4) is an expression, in terms of the upper-bend radii, for the maximum discharge per foot of crest that can obtain without exceeding the criterion for minimum absolute pressure. If Q represents the total discharge for which the siphon is being designed, the length of crest, or width of throat section, is given by

$$B = \frac{Q}{Q_1} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

The throat area to be provided is thus determined and equal to the width times the depth. Equations (4) and (5) are perfectly general and can be applied to the upper bend of any spillway whether it is a high-head or a low-head siphon. They indicate the discharge that can pass safely through the upper bend. The remainder of the siphon tube must be proportioned in such a manner that this discharge is not exceeded.

INLET

The next step is to provide a well-proportioned inlet. There is no "hard and fast" analytical method of procedure that can be followed in the design of this opening. As is the case in any conduit intake, it is desirable to keep the entrance velocity low and to avoid sharp corners where flow lines are curved. The inlet should be sufficiently removed from the head-water level to prevent the siphon from sucking air through the surface depression caused by the formation of a free vortex in the head-water bay. With low entrance velocities, however, the probability of having a pronounced vortex is lessened. Hydraulic considerations and experience with siphons have indicated that entrance losses are minimized when the inlet area is two or three times the area of the throat and is formed with well-rounded corners. To prevent the entrance of ice and drift, and to guard against surface disturbances, it is desirable to locate the opening in such a manner that it is at all times well below the water surface. Usually the inlet is protected by rack bars spaced quite far apart.

UPPER LEG

The design of this part of the siphon tube generally presents little difficulty. Probably the only requirement is that the upper leg should taper gradually from the inlet to the throat, thereby providing a smooth transition in which acceleration is affected.

LOWER LEG

Primarily the function of the lower leg of a siphon is to make possible the existence of the partial vacuum that must occur at the summit, and to provide a channel through which the water may escape and be directed to the point of discharge. In the case of a low-head siphon no especial difficulty need be experienced with the lower leg. It is simply a matter of making the tube uniform and equal in area to the throat section, and positive action can be expected. Frequently the lower leg is constructed to incorporate a gradual expansion in cross-sectional area thereby making use of draft action to increase the discharge. When the capacity of the spillway has been determined, the pressures developed at the summit should be investigated by application of Equation (4). If such analysis indicates that the absolute pressure is below the practical limit (say 10 ft), the upper bend should be redesigned to prevent the existence of undesirable negative pressures. For a high-head siphon, however, the problem becomes more involved and warrants a careful analysis. In a high-head siphon, if the lower leg were to be made equal in cross-sectional area to the throat section, and made uniform throughout, excessive vacuums would prevail. Air would be drawn from solution, cavitation would occur at points of reduced pressure, and parting of the water from the siphon tube could be expected. As a result siphonic action would be interrupted intermittently, with accompanying vibration and violent shock.

As has been explained previously, the maximum head that can be utilized to produce flow is 24 ft, plus the head lost due to friction, bends, entrance, etc. Consequently the total head available in excess of that amount cannot be used to increase the discharge of the siphon. That excess head may be expended in two ways: (1) A part of it can be dissipated by introducing resistances such as a bend and friction; and (2) the remainder can be converted into kinetic energy by increasing the velocity of flow at the outlet; that is, by reducing the cross-sectional area of the siphon tube near the outlet by means of a reducer. In effect these resistances provide sufficient back pressure in the lower leg of the siphon to keep the tube flowing full. The problem then is to determine the necessary reduction in outlet size to accomplish this without restricting the capacity of the throat opening.

The cross-sectional area of the throat, the upper bend radii, and the upper leg proportions have already been fixed. To facilitate the following derivation the lower leg is assumed to be equal in area to the throat opening and of uniform cross-section throughout. In this manner the problem is reduced to one that lends itself to analytical solution.

It is possible, now, to compute the head loss in the siphon tube for the discharge Q. The losses should include those due to entrance, friction, bends, and the discharge on exit loss. This determination involves merely a selection of head-loss coefficients and does not warrant further comment. All of the losses can be expressed as a percentage of the velocity head (h_v) in the throat section. Hence, if $K_1 h_v$ is the head loss due to the entrance, friction, bends, etc., and, $K_e h_v$ is the head converted into kinetic energy, then the total head lost is $K_1 h_v + K_e h_v$ or, $h_v (K_1 + K_e)$. It must be remembered that in this expression if no reducer were provided the value of K_e would be equal to unity. Assuming the siphon to discharge into atmosphere, it is evident that the total head lost must equal the total head available. In other words the hydraulic gradient must intersect the siphon tube at its outlet; thus:

$$H = (K_1 + K_e) h_v \qquad \text{(6)}$$

The exit loss coefficient may be expressed in terms of the reference area (the area A_t, at the throat) and the area of the reduced outlet, A_r; that is:

$$K_e = \left(\frac{A_t}{A_r}\right)^2 \quad \text{.......................(7)}$$

Substituting the value for K_e (Equation (7)) in Equation (6):

$$H = \left[K_1 + \left(\frac{A_t}{A_r}\right)^2\right] h_v \quad \text{.......................(8)}$$

and, solving for A_r:

$$A_r = A_t \sqrt{\frac{h_v}{(H - h_v K_1)}} \quad \text{.......................(9)}$$

Thus, the area to which it is necessary to reduce the siphon tube at the outlet can be expressed in terms of quantities given in the basic data or determined from the foregoing calculation. By use of Equations (4), (5), and (9) the proportions of a high-head siphon spillway can be determined.

SOLUTION OF A SPECIFIC PROBLEM

In order to clarify the application of the method presented herein the following concrete example is solved completely. The basic data chosen are: (1) The discharge for which the siphon is to be designed is 350 cu ft per sec; (2) the outlet is to discharge into atmosphere; (3) the head available is 80 ft; (4) the permissible negative pressure is 24 ft of water; and (5) to compute the head lost due to frictional resistance a value of 0.012 is used for Kutter's *n* (this is a fair value in practice for a tube lined with cast iron). Detailed mention of the individual head losses is believed unnecessary. In the selection of head-loss coefficients, it is interesting to note that even sizable errors (for instance, using an *n* value of 0.020 instead of 0.012, for friction loss) have but little effect upon the hydraulic performance. If the coefficients used are too large, the actual discharge and velocities realized will be slightly greater than computed, thus increasing the total head lost. These effects are interrelated and tend to offset each other, with the result that a balance is reached at a discharge not far in excess of the original design value. A similar readjustment will occur if the coefficients used in the design computations are smaller than the actual values in the finished structure. Let it be assumed that consideration of the priming qualities desired and the physical limitations of the structure, as well as other factors, have fixed the radii of the upper bend as 4 ft and 7 ft. The problem is to determine the proportions of the siphon spillway so that the required capacity is obtained with satisfactory hydraulic performance. Fig. 2 is a graphical representation of the basic data selected. The form of the siphon tube was chosen at random and does not follow the pattern of any existing structure.

The first step is to determine the size of throat opening necessary so as not to exceed practical limitations on the minimum permissible absolute pressure at the crest. Equations (4) and (5) are derived in such a manner that the throat dimensions obtained by their application will conform to the fore-

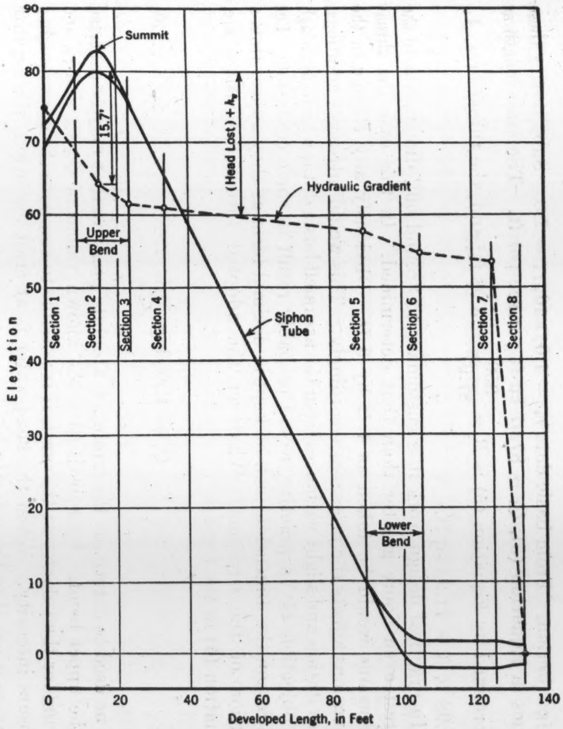

FIG. 3.—PLOT OF COMPUTED HYDRAULIC GRADIENT (DISCHARGE, 350 CUBIC FEET PER SECOND; AND POOL ELEVATION 80 FEET)

going criterion. From basic data $r_c = 4.0$; and, $r_s = 7.0$. Substituting these values in Equation (5), $Q_1 = 87.97$ cu ft per sec per ft. The crest length as determined by Equation (5) is $B = \frac{350}{87.97} = 3.98$ ft; and, the throat area, A_t, is $3.98 \times 3 = 11.94$ sq ft.

In practical design work it is customary to "round off" dimensions to the nearest even figure greater than that determined. In this case the throat dimensions would be taken as 4 ft by 3 ft. Obviously any change in the dimensions affects the pressures accordingly. This would introduce additional computation and slight variances from the assumed basic data, which, although not objectionable in practice, would probably result in some confusion. For this reason the dimensions will be kept in decimal form as they appear from a solution of the equation. Whatever the adopted throat dimensions are, Equation (4) in the form

$$Q_1 = V_c \, r_c \log_e \frac{r_s}{r_c} \qquad (10)$$

can be used to determine the minimum absolute pressure that may be expected in the upper bend. By substituting the known values of Q_1, r_c, and r_s, and solving for the velocity at the crest, it is possible to compute the corresponding pressure intensity. When the head-water is at crest elevation, the negative pressure is equal to the velocity head.

The next step is to provide some form of inlet and to fix the proportions of the upper leg. As stated previously, the design of this part of the siphon tube does not lend itself to analytical solution. Good judgment, experience, consideration of hydraulic performance, and limitations of the individual problem serve to guide the engineer in the design of the upper leg. To provide an area of from two to three times the area of the throat, an inlet opening 5 ft by 6 ft is selected. This will furnish an area of 30 sq ft or slightly greater than 2.5 times the area of the throat. Fig. 2 indicates the configuration of the spillway from the inlet to the crest section.

In the design of the lower leg the problem is to keep the tube flowing full; in other words, sufficient resistance to flow must be provided so that there is no tendency toward an increase in flow with its inevitable encroachment upon the minimum permissible absolute pressure. This desired back-pressure is created partly by frictional resistances which result in the dissipation of energy in the form of heat, and partly by the resistance offered by a reduction in outlet area which causes the remainder of the excess head to be converted into kinetic energy. To all intents and purposes the siphon tube is analogous to a large pipe line, and the total head lost plus that converted into velocity must equal the total head available. To facilitate solution of the problem let it be assumed that a transition in shape is effected between Section 3 and Section 4. Section 3 is identical to the throat section whereas Section 4, although equal in area to the throat opening, is circular. Furthermore, let it be assumed that the tube is uniform in cross-section from Section 4 to the outlet. It is possible now, having the proportions fixed, and having the discharge, to compute the losses that occur in the entire structure. The order and magnitude of these losses, as computed for the problem at hand, are recorded in Table 1.

* Velocity in the reduced outlet area.

The values shown in Column (6), Table 1, represent the total head lost between sections expressed as a percentage of the velocity head in the throat section. A summation of the quantities in Column (6), Table 1, gives the value of K_1 in Equation (9) when $A_t = 11.94$ sq ft; $H = 80.0$ ft; $K_1 = 103.5\%$ (the summation of Column (6)); and, $h_v = 13.3$ ft. Substituting these values in Equation (9), it is found that the area to which the outlet must be reduced is 5.35 sq ft, or the diameter of the outlet will be 2.61 ft. Thus with the determination of the outlet size the problem is solved. Usually the outlet piece is a special casting and can be made to furnish the exact area required. The purpose of the reducer or choke at the outlet is to avoid excessive negative pressures, which result in unsatisfactory hydraulic performance. If an area greater than that determined herein is selected, smooth action in the operation of the spillway would be jeopardized. On the other hand, if greater constriction is provided, other conditions being equal, the only adverse effect would be a reduction in the spillway capacity. This is undesirable economically since the remainder of the siphon tube is not being used to the greatest advantage.

In the computation of the head losses appearing in Columns (2), (3), (4), and (5), Table 1, the writer used standard forms accepted in practice. The actual coefficients used are not shown since it is believed that a discussion relative to the evaluation of head losses might detract from the original purpose of the paper. Other ramifications might be introduced such as moving the reducer nearer to the throat or providing a gradual taper instead of a relatively sudden contraction. The writer is confident that the problem, as solved herein, together with the simplifying assumptions introduced, serves adequately to elucidate the fundamental principles involved. The engineer frequently finds it necessary to use the standard pipe available in stock sizes. This may be done, but caution must always be used and the final layout must be investigated to be sure that the revised proportions do not induce pressures below the minimum permissible absolute pressure.

Columns (7) to (11), Table 1, are self-explanatory and were computed so that a plot of the hydraulic gradient could be drawn. Since Column (6) represents the total head lost between sections, expressed as a decimal fraction of the velocity head in the throat section, Column (7) is obtained simply by multiplying the values in Column (6) by 13.3 ft, or the velocity head in the throat section. The drop in the hydraulic gradient from the level of the headwater surface at any section is equal to the sum of the accumulated losses plus the velocity head at that section. Using the center line of the outlet as datum, Column (11) shows the elevation of the hydraulic gradient at any section. A graphical plot of the gradient is shown in Fig. 3 and illustrates quite clearly its limitations as well as its application. The condition of flow in the upper and lower bends is such as to invalidate the pressures shown by the computed hydraulic gradient in those regions. For the sake of illustration the siphon tube is distorted by plotting length along the spillway axis as the abscissa against elevation as the ordinate. With such an arrangement it is possible to measure pressures at any point along a vertical line. The preceding text has demonstrated that a computed hydraulic gradient could not be utilized to predict localized pressure intensities at the crest. In Fig. 3 it would seem that the negative pressures to expect at the crest and the crown at the summit would be 15.7 ft and 18.7 ft of water, respectively. Actual prototype measurements and model experiments prove conclusively that such deduction is erroneous. The order of magnitude of pressure variations in the upper bend, as computed by assuming free vortex flow, gives results closely in accordance with actual flow conditions. In the basic data for the problem under consideration the outlet was assumed to be discharging into atmosphere; hence the hydraulic gradient must intersect the siphon tube at its outlet. Fig. 3 indicates how the formula derived and the procedure outlined so adjusts the proportions of the spillway that for the design discharge of 350 cu ft per sec the head losses sustained through the entire structure, plus the exit velocity head, bring the gradient down to the proper elevation at the outlet.

In this paper the writer has intentionally made little or no reference to details such as priming, air vents, ejectors, sealing basins, etc. (A. H. Naylor in 1935[2] and the late G. F. Stickney, M. Am. Soc. C. E., in 1922,[4] have offered excellent discussions of these features.) This was done, not because they are unimportant, but because the phase of siphon design dealt with is complete without them. Naturally each high-head siphon spillway that is designed presents individual problems. The writer does not wish to create the impression that the simple application of the specialized formulas constitutes an "iron-clad," fool-proof method of solution. It is necessary to have a clear conception of the laws governing siphonic action as well as an understanding knowledge of basic hydraulic principles involved.

---

[4] *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1098.

CONCLUSION

In the design of a high-head siphon spillway for which it is desired to fix the proportions so that a definite capacity can be provided, there are two considerations of paramount importance: (1) The provision of adequate cross-sectional area at the throat, thereby preventing the occurrence of excessive negative pressures; and (2) the provision of a reduced outlet area to prevent excessive pressures and consequent intermittent and highly unsatisfactory operation.

The first requirement can be met by assuming free vortex flow in the upper bend. Such an assumption very closely approximates actual flow conditions in that part of the siphon tube. A study of the hydraulic gradient will not reveal true localized pressure variations at the summit.

To determine the proper degree of constriction at the outlet without encroaching upon the full capacity of the throat opening it is necessary to analyze the head losses in the siphon and so adjust the outlet area that the hydraulic gradient intersects the lower leg at its extremity. If the siphon does not discharge into atmosphere the gradient must indicate the pressure at the outlet.

ACKNOWLEDGMENT

The writer is indebted to John B. Drisko, Jun. Am. Soc. C. E., for his constructive criticism and helpful suggestions.

DISCUSSION

J. C. Stevens,[5] M. Am. Soc. C. E. (by letter).—Two outstanding features of this paper are its clarity and brevity. May this discussion be as concise.

It will be of interest to compare the ideological design presented by Mr. Rock with the behavior of the Leaburg[6] and Walterville[7] siphons on which field tests have been made and fully described in the Society's publications.

The writer has set forth the basic principles of siphon behavior in a paper published in 1933.[6] The author's "high-head" siphon corresponds to the case in Fig. 10 of that paper when Section 3 coincides with or lies below Section 2, and the "low-head" siphon when Section 3 lies above (submerges) Section 2.

An important fact in siphon behavior which the author has failed to take into consideration is that the siphon barrel is occupied only in part by water moving down stream and in part by eddies. Fig. 3 of the writer's paper[6] illustrates an idealized concept of the effective and non-effective areas of the Leaburg siphons.

In 1938[8] data were presented to show the eddy area at each cross-section indicating a maximum of 28% of non-effective area. The effect of this phenomenon is to nullify, largely, the author's calculations as to a limiting velocity within the barrel.

The writer will hazard the guess that, if the siphon illustrated by Mr. Rock in Fig. 2 were in use and under observation, the maximum mean velocity would be found, not at the summit section, but somewhere in the lower leg and that its value would be 40 ft per sec or more. Table 2 shows that the maximum mean velocities in the Leaburg and Walterville siphons were from 23% to 55% greater than the mean velocities in the summit sections and that they occurred well down in the lower leg. During this acceleration the jet must suffer a contraction and leave eddying water around it. The continuity law "$Q = A V$" holds only if A is the area of the jet and not that of the barrel.

The author's assumption that the velocity distribution through the summit section follows the free vortex law, wherein the radial acceleration $v r$ is constant, is not substantiated by the tests. Table 2 also gives the velocities at the crowns and inverts of the five siphons tested, determined from the piezometer readings at these points. The data may be verified from Table 2 and Figs. 7, 8, and 9 of reference given in Footnote 6, and Table 1 and Fig. 7, of reference given in Footnote 7. Note that the radial acceleration at the crowns is from 14% to 35% greater than at the inverts.

The necessity of admitting water to the summit section through a priming conduit is one factor that may nullify the application of the vortex principle.

The author is correct in stating that the head on a siphon may exceed that of an atmosphere. The highest head that can be utilized is one atmosphere minus vapor pressure of the water plus all entrance, friction, bend, eddy losses, and exit velocity head. On the Walterville siphons the head is nominally 46 ft. There is no shock or vibration or other evidence of a disconnected water column.

The writer can see no value in contracting the outlet to consume head. If 80 ft of head were available it would be far more practicable to discharge the siphon into an open chute after using 40 ft or so for the siphon head. Open conduits are much cheaper than siphon barrels. This plan was followed at Walterville. In the final stage of reconstruction the tail-water is to be lowered about 7 ft and a chute built from the end of the siphon barrel,[9] to discharge the water well below the water surface, absorbing the energy by an hydraulic jump.

B. E. TORPEN,[10] M. AM. SOC. C. E., G. E. HYDE,[11] JUN. AM. SOC. C. E., and R. B. COCHRANE,[12] ASSOC. M. AM. SOC. C. E. (by letter).—The approach to the problem of siphon spillway design presented in this paper may prove meritorious. Equation (4), based on the assumption that free vortex flow prevails in the bend of the throat section of a siphon spillway is a simplifying step, and

¶ Velocity head computed as the difference between the energy gradient and the hydraulic gradient.

results in doing away with the necessity of selecting a "coefficient of ignorance" masked under the name of Flow Coefficient. Therefore, his attempt to rationalize the common procedure of design for throat sections of siphon spillways is worthy of commendation.

Vortex Flow Assumption.—Certain questions and doubts arise, however, concerning the soundness of the author's assumption of vortex flow in siphon throat sections, and concerning the practical application of his formula in the design of siphon spillways. In an attempt to answer these questions and to eliminate these doubts, the velocity distributions, as they actually exist in the throat sections of three different siphon spillways[13] were compared, respectively, to the velocity distributions as computed from Mr. Rock's formula (see Equation (10)):

$$V = \frac{Q}{r \log_e \frac{r_s}{r_c}} \quad \text{.........................} (11)$$

The numerical calculations involved in this comparison are given in Table 3 and the results are portrayed graphically in Fig. 4. Table 3 first lists the actual operating conditions of the three selected siphons. These data were used in Mr. Rock's formula to compute the velocities at the crest, mid-section, and summit of each siphon throat section. A second set of similar velocities at these points was then computed by subtracting the actually measured hydraulic gradient from the energy gradient. That is,

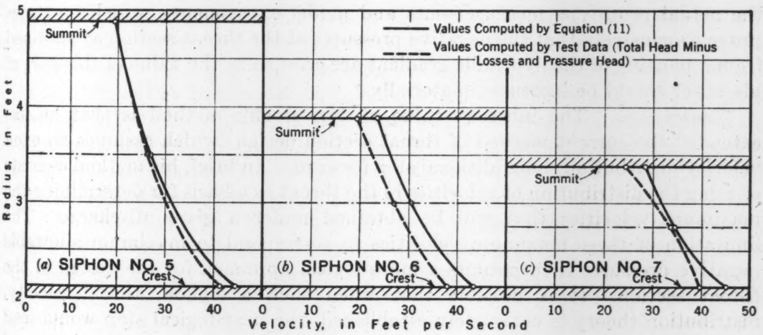

FIG. 4

$$\frac{V^2}{2g} = H_e - \left(Z + 33 + \frac{p}{w}\right) \quad \text{.................} (12)$$

Comparison was finally made between the two sets of velocities by percentage difference in order to obtain an index as to the validity of Mr. Rock's formula.

---

[13] "On the Behavior of Siphons," by J. C. Stevens, M. Am. Soc. C. E., *Transactions*, Vol. 99 (1934), p. 986.

Arithmetically:

$$\text{Percentage difference} = \frac{V_{\text{Rock}} - V_{\text{actual}}}{V_{\text{actual}}} \dots\dots\dots\dots (13)$$

It will be noted from Fig. 4 that in all three cases, the actual velocity values, as derived from the test data, are greater at the crest than at the summit, and that the velocity values as computed by the author's formula (Equation (11)) conform fairly well with the so-called actual values. When the number of ways in which experimental and personal error may have entered into the test data are considered, the comparison in Fig. 4 is believed to be surprisingly good; and, furthermore, this comparison appears to be a strong indication that the author's assumption of vortex flow is justified. In addition to the foregoing comparison, the practical application of Mr. Rock's formula was tested by checking the throat sections of several other existing siphon spillways. It was found that the computed and actual values checked quite satisfactorily.

Further Considerations.—The author's treatment of the importance of proper lower leg design in high-head siphons is considered good. The mathematics involved in this phase, as well as those concerning the derivation of his vortex flow formula, were found to be valid. The numerical solution of the example siphon, as given by Mr. Rock, aptly illustrates his point that a plot of the hydraulic gradient does not result in true negative pressures at the crest and summit of the throat section. However, if the author had included in his text the actual prototype measurements and model experiments, which he states prove conclusively that the negative pressures at the throat section as obtained from a plotting of the hydraulic gradient are erroneous, the value of this part of his paper would be increased materially.

Conclusions.—The inherent value of Mr. Rock's method is that he has extended the current method of throat section design (which assumes an even velocity distribution) an additional step forward. In brief, his method consists of using the distribution of velocities in the throat as a basis for determining the maximum velocities that will be obtained under a given discharge. The limitation of these maximum velocities to correspond to maximum allowable negative pressures then permits a more logical approach for the design of the throat section. It is possible that when such a siphon, throat-velocity, distribution theory is completely established, the next logical step would lead to an attempt to increase the efficiency of siphon operation by redesigning the throat section into other than a rectangular or circular section. Such a design, of course, would have to result in a gain in efficiency of operation sufficient to overcome increased construction costs.

I. M. Nelidov,[14] Assoc. M. Am. Soc. C. E. (by letter).—Not only does the paper demonstrate the design of a particular siphon, but it also contains a theory with general rules intended for the design. The author has based his statements on an ideal case of a frictionless siphon, consisting only of the throat section. For this case he determines the theoretical velocity based on full vacuum head, and the resulting discharge. He also classifies as "high-head" siphons those which have operating heads greater than 34 ft. Furthermore, he has selected a siphon with an 80-ft head of fairly uniform cross-sections, with the exception of the outlet section, which he throttled in order to fill the outlet leg; and he classifies it as a "high-head" siphon.

---

[14] Senior Engr. of Hydr. Structure Design, State Div. of Water Resources, Sacramento, Calif.

Under "Introduction" the author states: "The term 'high-head siphon' is used by the writer to denote siphons that operate under heads in excess of 34 ft, or the barometric height"; and, under "Upper Bend and Throat": "As a general rule experience with siphon spillways has established 24 ft of water as a maximum negative pressure to be allowed at any point in the structure."[3] It is not clear from the foregoing which of the two heads (24 ft or 34 ft) should be used in defining the high-head and low-head siphon.

Mr. Rock qualifies the conditions for an ideal frictionless siphon without outlet, as stated herein. This may be satisfactory for the purpose of design but is not acceptable for the purpose of checking when one must classify an existing siphon and obtain the discharge on the basis of this classification.

Referring strictly to terminology, one may ask why, for instance, a 50-ft head should be called a "high head." In reference to dams at which siphon spillways mostly occur it cannot be called a high head. Perhaps heads beginning with 100 ft or 150 ft should be called high heads.

The dividing line, in the opinion of the writer, lies not in the head but in the functioning of a siphon. To illustrate, a siphon with an operating head of 10 ft and in which there is a considerable contraction at the summit will create a limiting velocity; and a further increase of head more than 10 ft will not produce any increase of flow. Under the same head, if the maximum contraction is made at the outlet, the maximum velocity will not be developed. On the other hand, a siphon under 100 ft of head and with a maximum contraction at the outlet may not produce the limiting velocity; and, further increase or decrease of the operating head will produce a change in the discharge. If the outlet is sufficiently constricted this siphon will develop the maximum velocity.

Consequently, independently of value of the operating head, a siphon may flow with a limiting velocity and without an increase of discharge due to further increase of the head; or, it may flow with a velocity below the limiting value, discharge being affected by increase of the head. The writer proposes to divide the siphons into two classes depending upon whether the operating head is greater or less than the limiting head at which the siphon produces limiting velocity. Thus, siphons may be classed according to whether their discharge is equal to or lower than the maximum discharge. The head at which this division occurs may be called the "limiting head." It should be made clear that the limiting head should not be related to any definite value of 24 ft or 34 ft, but that it should be taken as the head producing the limiting velocity. As mentioned previously herein, the classification should be made general both from the standpoint of design and checking, so that by reviewing an existing siphon one may also be able to classify it.

As to the theory proper, it may be noted that if the postulates of the author about the position and magnitude of vacuum are temporarily accepted the following derivations will be produced.

The limiting head will be (see Equation (6)):

$$H_{\text{lim}} = (K_e + K_1\, n)\, h_v \ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

in which: K_1 and K_e are as denoted by the author; h_v is the velocity head at the throat corresponding to mean velocity, V_m; and n is a coefficient in the expression:

$$E_k = n\, h_v \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

in which E_k is the average kinetic energy of the curvilinear flow per unit of flow, such that[15]

$$E_k = \frac{\displaystyle\int_0^d \frac{V^3}{2\,g}\,dy}{\displaystyle\int_0^d V\,dy} \ldots\ldots\ldots\ldots\ldots\ldots (16)$$

In order to understand, better, the conditions existing at the throat, and using the criterion that the absolute pressure at crest of the throat should not be less than zero, one may draw Fig. 5. The notation is by Boris A. Bakhmeteff,[15] M. Am. Soc. C. E., and the author.

Then, denoting $m = \frac{r_s}{r_c}$ and

$$\beta = \frac{V_s}{V_m} = \frac{1}{\frac{r_s}{d}\log_e \frac{r_s}{r_c}} \ldots\ldots\ldots\ldots\ldots\ldots (17)$$

integration of Equation (16) yields:

$$n = \frac{\beta^2}{2} \times \frac{m^2 - 1}{\log_e \frac{r_s}{r_c}} \ldots\ldots\ldots\ldots\ldots\ldots (18)$$

---

[15] Discussion by Boris A. Bakhmeteff on "Tests of Broad-Crested Weirs," by James G. Woodburn, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 423.

The criterion for zero absolute pressure at the crest of the throat is:

$$h_a + h_{pr} = h_{vc} + n\, h_v\, K_1' \qquad (19)$$

in which: h_a is the atmospheric head; h_{pr} is the priming head; $h_{vc} = m^2 h_{vs} = m^2 \beta^2 h_v$; and K_1' is the sum of the coefficients of loss from inlet to crest, referred to mean velocity of the throat. Substituting

$$h_v = \frac{h_a + h_{pr}}{m^2 \beta^2 + n\, K_1'} \qquad (20)$$

from Equation (19) into Equation (14):

$$H_{\text{lim}} = (K_e + K_1\, n)\, \frac{h_a + h_{pr}}{\beta^2 m^2 + n\, K_1'} \qquad (21)$$

The discharge per linear foot of the crest, with velocity $V_m = \sqrt{2\, g\, h_v}$, will be:

$$Q = d V_m = d \sqrt{\frac{2\, g\, (h_a + h_{pr})}{\beta^2 m^2 + n\, K_1'}} \qquad (22)$$

which reduces to Equation (4) if $h_{pr} = K_1' = 0$. Applying Equations (14) to (22) for the particular siphon in consideration: $K_1 = 1.035$; $K_1' = 0.154$; $K_e = 4.980$; $m = \frac{7}{4} = 1.75$; $d = 3$ ft; $h_a = 24$ ft; and $h_{pr} = 0$. Then, by Equation (17), $\beta = 0.770$; $\beta^2 = 0.593$; and $m^2 = 3.060$. Furthermore, by Equation (18): $n = 1.090$; and, by Equation (21), $H_{\text{lim}} = 78.5$ ft < 80 ft.

Consequently, the siphon as designed by the author is a "high-head" siphon by only a very small margin. The means by which the limiting head was raised to 78.5 ft is somewhat artificial and consists in throttling of the outlet section only. Otherwise, this siphon would definitely fall into the "high-head" class. In this case, with $K_e = 1$, the limiting head will be $H_{\text{lim}} = 26$ ft.

It would be better to designate this siphon as one belonging to a class with maximum discharge. The limiting discharge corresponding to a head of 78.5 ft, by Equation (22), will be: $Q = 3 \sqrt{2\, g\, \frac{24}{3.050 \times 0.593 + 1.090}} = 3 \times 29.9 = 84$ cu ft per sec per ft. This is the maximum discharge that this siphon will produce, disregarding the further increase of the operating head.

In regard to the limits of applicability of Equation (4), it may be noted that with a constant depth of the throat "d" the discharge Q_1 decreases with the decrease of r_c, and does so especially rapidly for the ratio $\frac{r_s}{r_c} < 2$.

With a sharp crest such as may occur in a siphon with a vertical barrel, $\frac{r_s}{r_c} = \infty$ and, theoretically, the discharge approaches zero. Actually, however, there will be some flow through the siphon. A cavity will form above the sharp crest, producing some minimum radius r_c, depending on the conditions of the inlet. Consequently, if a siphon under consideration has an exceedingly small radius, r_c, it should be verified that the latter is greater than its allowable minimum if an expression for flow similar to Equation (4) is to be applied safely. The value of r_e (min) may be determined with the aid of the momentum principle used for entrance and throat sections.

The ratio of radii selected by the author is: $k = \frac{r_c}{r_s} = \frac{4}{7} = 0.570$. This is not the ratio, however, that gives the maximum discharge. From Equation (4) it follows that the discharge reaches its maximum value with a certain value of ratio k, r_s being constant. Representing Q_1 as a function of k:

$$Q_1 = 39.5\, r_s\, F(k) \qquad (23)$$

in which $F(k) = k \log_e \frac{1}{k}$. Differentiating F by k and equating it to zero, the value $k = 0.367$ produces the maximum value of $F_{max} = 0.368$; and Q_1 (max) $= 103$ cu ft per sec per ft. In this case the radius at the crest should be $r_c = 0.367 \times r_s = 2.57$ ft, and the depth of the throat should be $d = r_s - r_c = 4.43$ ft, against $d = 3$ ft, selected by the author. It would be interesting to compare the author's basis for selecting the radii.

The position of the maximum vacuum within the siphon, so far as it may be determined for siphons with straight outlet leg, is at the crest of the throat section.[3, 16] In the siphons with another convex-upward curvature, besides the throat proper, situated down stream from the latter and without throttling at the outlet end maximum vacuum is developed at the section somewhat down stream from the throat section.[7] This is due to an unrestricted increase in velocity and could be relieved by throttling the outlet section. Therefore, apparently the position of maximum vacuum at the crest is justified for a siphon with straight outlet leg.

The magnitude of the maximum relative negative pressure is limited, by the author, to 24 ft. This value acquires significance for computing the "limiting head" and the maximum discharge. It becomes especially important for siphons at high elevations. For instance, at an elevation of 6 000 ft the vacuum head is normally reduced from 34 ft to 27 ft. If, then, 10 ft should be deduced from it for vapor pressure and other imperfections, it will leave only 17 ft as actual vacuum head. It is of importance, therefore, to make the recommendation as to the limit of the vacuum head to be used at different elevations more specific.

Prof. A. N. Gibson[3] states: "With reference to the limit of velocity at the throat of the siphon the maximum velocity should not be higher than would cause a negative pressure greater than about 24 feet of water." Mr. A. H. Naylor, one of the discussers of Professor Gibson's paper, states: "The pressure was lowest on the inside radius and that minimum pressure must not be less than a vacuum of about 28 feet of water." B. A. Etcheverry,[17] M. Am. Soc. C. E., states: "In practice on account of the air entrained in the water, the maximum suction lift is often taken as about 28 feet."

It follows from the foregoing citations that recommendations for vacuum head vary from 24 ft to 28 ft. On the other hand, during experiments made by

---

[16] "Hydraulic Laboratory Practice," by the late J. R. Freeman, Hon. M. Am. Soc. C. E., pp. 515 and 610.

[17] "Irrigation Practice and Engineering," by B. A. Etcheverry, and S. T. Harding, Members, Am. Soc. C. E., 2d Ed., McGraw-Hill Book Co. Inc., New York, N. Y., 1933.

J. C. Stevens,[7, 13] M. Am. Soc. C. E., negative pressures of about 32.5 ft were actually observed at Elevation 700 above sea level, all of which shows the variety of numerical values suggested for vacuum head. There is a need for a more precise definition of the vacuum head based more on experimental data than has been produced to date. Consequently, it would be valuable to receive from the author a more complete description of data upon which he recommended 24 ft of vacuum head with such confidence.

In conclusion, the writer wishes to say that the value of the proposed theory should be proved in checking the computed discharges with the discharges actually observed. He has selected the papers[7, 13] by Mr. Stevens for this purpose, using the observed maximum negative pressure at the crest as the velocity head h_{vc} (omitting losses from the entrance to the throat).

Siphons Nos. 5, 6, and 7, reported by Mr. Stevens, gave the discrepancies from the observed discharges as 0, −2, and 12 per cent. Siphons Nos. 1 and 2 reported in a second paper indicated a discrepancy of −6% and 0 per cent. This indicates that, at least for this type of siphon, the agreement of theory and practice is fairly satisfactory.

ELMER ROCK,[18] JUN. AM. SOC. C. E. (by letter).—The discussions are of a high caliber and were written by engineers well qualified to criticize, constructively, siphon design procedure. Unquestionably the value of the paper has been greatly enhanced by these contributions.

Mr. Stevens has selected Siphons Nos. 5, 6, and 7 at Leaburg, and the two siphons at Walterville for the purpose of comparing prototype measurements with predicted velocities based on assuming free vortex flow in the upper bend. He emphasizes the fact that in these particular siphons the barrel is occupied only in part by water moving downstream and in part by eddies. It is doubtful that the designer of these siphons intended to have a portion of the tube noneffective. This phenomenon is not characteristic of all siphons. At Leaburg the total head is approximately 27 ft and one would not expect separation of the jet from the siphon tube. However, upon investigation it is found that the cross-sectional area of the tube at the outlet is 1.5 times the throat area. The jet issuing from the throat section is unable to follow the expanding barrel, under those conditions, with the result that part of the area is rendered noneffective, velocities are increased, and extremely low absolute pressures are developed. At Walterville the total head is approximately 46 ft and the lower leg has a constant area throughout its length. In this case separation of the jet from the barrel of the siphon could be prevented by tapering the lower leg so that the outlet area is reduced. In the opinion of the writer a siphon, in order to operate smoothly and without vibration, should be designed to eliminate parting of the water from the siphon tube, cavitation, and the presence of eddies or turbulent water pockets.

When the water leaves the invert of the upper bend, as it does at Walterville and Leaburg, a new boundary is formed and its radius is no longer equal to the radius of the invert, but somewhat greater. It is difficult to determine the exact value of this increased radius. Accordingly, the values of r_2 that Mr. Stevens used in Table 2 are not correct and the values for radial acceleration at the crest are misleading. It is obvious that if r_2 is increased the radial acceleration ($V_2\ r_2$) will increase, resulting in better agreement with the radial acceleration at the crown. Aside from this there are other variations that should be considered. For instance, it may not be justifiable to place full trust in prototype measurements where near absolute zero pressures exist and flow conditions are extremely disturbed. In his tests[19] Mr. Stevens has found that a piezometer connection registering very low absolute pressure would suddenly spout water up in to the mercury gage. This indicates that conditions are highly unstable in the upper bend of a siphon in which the jet is allowed to separate from the walls, and measurements made under such circumstances might not be entirely reliable. From the foregoing it follows that Mr. Stevens has not shown conclusively that the assumption of free vortex flow in the upper bend of a siphon is invalid.

---

[18] Hydr. Engr., U. S. Engr. Dept., U. S. Engr. Office, Providence, R. I.

Flow conditions in a pipe bend (such as the upper bend of a siphon) are very complex and are not susceptible of exact mathematical analysis. The problem is made even more complex when the velocity distribution in the conduit, as it approaches the bend, is unbalanced. The shape and alinement of the conduit immediately down stream from the bend likewise influence the flow around the bend. Mr. Stevens states: "The necessity of admitting water to the summit section through a priming conduit is one factor that may nullify the application of the vortex principle." Not all siphons have priming conduits which permit water to enter in this manner. Naturally, in those that do have such provision, there is a tendency further to complicate the velocity distribution in the upper bend. According to the analysis made by Messrs. Torpen, Hyde, and Cochrane, shown graphically in Fig. 4, the effect of such admission of water in the Leaburg siphons does not influence the velocity distribution enough to nullify the application of the vortex principle.

The writer disagrees with Mr. Stevens in the contention that a mean velocity of 40 ft per sec or more would be found in the lower leg if the siphon used for illustration were in use and under observation. Perhaps this would be true if the outlet were not reduced in area. To omit the reducer would result in some increase in discharge which in turn would be accompanied by pressures close to absolute zero and separation of the water from the walls of the siphon barrel. In this case a contracted effective area might well give mean velocities as high as 40 ft per sec. The siphon designed in the problem selected for illustration, however, will discharge no more than 350 cu ft per sec, and it is the writer's contention that such a discharge (in an upper bend of the dimensions given) will not produce the phenomenon discovered at the Walterville and Leaburg siphons.

It has been reported that the Walterville siphons vibrate to a certain extent at full flows.[20] It is reasonable to attribute such vibration to the unstable condition of flow mentioned in the foregoing paragraph.

It is true, as Mr. Stevens states, that open channels are cheaper than siphon barrels. There are many instances, however, in which the flow must be carried to the point of discharge in a closed conduit. For example, consider the case of a dual-purpose reservoir built primarily for flood control, but which at the same time is to create a lake for recreational purposes. The dam is an earth-fill embankment with the conventional flood outlet consisting of a tunnel with a gate control-tower located approximately at its mid-point. A siphon spillway, to regulate the level of the recreation pool, is to be incorporated in the tower. It draws water from the emergency gate wells and discharges into the tunnel down stream of the service gates. For a project of this description there is no alternative; the flow must be carried in a closed conduit.

[19] "On the Behavior of Siphons," by J. C. Stevens, *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 998.

[20] *Loc. cit.*, Vol. 104 (1939), p. 1805.

When the writer first used the free vortex theory in analyzing flow conditions in the upper bend of a siphon, he too was skeptical as to its usefulness. After making several comparisons with actual test data there remained no question as to its value. The reaction on Messrs. Torpen, Hyde, and Cochrane apparently was similar. It is undoubtedly true that the paper would have been more convincing if comparison with actual measurements had been presented. It should be remembered, however, that the upper bend of a siphon is only a bend in a closed conduit, and that free vortex flow has been shown to approximate, closely, the actual velocity distribution in bends by others. Nevertheless the comparison given by the authors will be of value to those who doubt the application of the vortex theory. Once it has been shown that the velocity distribution at the summit section is far from uniform (and this is now definitely established) it follows that a plot of a computed hydraulic gradient based on mean velocities will not reveal the true diminution of absolute pressure intensities in the upper bend.

Mr. Nelidov disagrees with the application of the term "high-head siphon." He proposes to apply this term only to those siphons in which the operating head exceeds the "limiting head." As defined, the limiting head is that which develops the maximum discharge capacity of the siphon. In order to compute it the dimensions of the siphon to be classified must be known. In other words, a siphon would have to be designed first and then classified. According to this reasoning any siphon could be either put into, or taken out of, the high-head class by making some small dimensional changes. For instance, the siphon used for illustration by the writer would cease to be a high-head siphon if the outlet area were reduced slightly. This makes Mr. Nelidov's definition seem irrational. The classification according to head as interpreted by the writer is by no means new. Perhaps to restate the definition in a little different manner will serve to clarify its meaning—a siphon naturally falls into the high-head class where the operating head is so great that, to get good performance (and this means that a break in the water column or its separation from the conduit walls is prevented), special provision must be made to consume excess head. Throttling the outlet is a convenient way to expend excess head.

The diagrammatic sketch in Fig. 5 is very comprehensive and will aid the designer in visualizing flow conditions in the upper bend. The writer has followed through Mr. Nelidov's derivation and finds that it is mathematically correct. It is important to note that the entire procedure is predicated on the same assumptions relative to flow in the upper bend as made by the writer; namely, that velocity distribution is according to the free vortex theory. Except for a slight rearrangement of terms, Equation (17) is the same as Equation

(10). Where the variation in velocity in curvilinear flow can be expressed as an equation it is possible to determine, mathematically, the average kinetic energy per unit of flow. In this manner Equation (16) is useful for the case at hand. Mr. Nelidov illustrates how the priming head and the head losses from the inlet to the throat can be included in the computations. There is some question as to whether it is justifiable to include such small forces when the basic assumptions regarding flow are only approximate, and the head losses involved are difficult to evaluate. Actually the elevation of the forebay and the head lost in the siphon are directly related to the pressure at the summit section. It may not be commensurate, however, with the general accuracy of the method to compute the effect of priming head and head losses in the upper leg which, incidentally, act to offset one another. In the problem used for illustration the only effect that neglect of these factors has is to increase the negative pressure at the throat slightly. Since the permissible negative pressure of 24 ft of water has a factor of safety in it, this is inconsequential. The capacity remains unchanged.

The value K_1' from Table 1 is the sum of the losses between Section 1 and Section 2, and should be 0.186 instead of the 0.154 used by Mr. Nelidov. In checking through the arithmetic the writer finds that Equation (21) yields a value for H_{llm} of 73.9 instead of 78.5. The substitution in Equation (22) as shown is incomplete, but the answer is correct.

Mr. Nelidov calls attention to the limitations of Equation (4). Naturally when r_c becomes zero (that is, the crest is a knife-edge) Equation (4) gives a discharge of zero. This is true because, theoretically, water moving at any finite velocity, no matter how low, cannot change its direction without some curvature, however small the radius may be. In the opinion of the writer, except where hydraulic performance is of no consequence, the upper bend of a siphon should be formed with regular curves of moderate radii so that the formation of cavities is prevented. It is now a matter of common knowledge that the discharge increases when a cavity (space filled with eddying water) of this nature is filled with masonry, in spite of the fact that the flow cross-section is contracted. Equation (4) will be valid under these conditions. At the same time the writer recognizes that siphons have been built, and will be built, with exceedingly sharp crests, and that in checking the performance of these siphons the minimum value of r_c, as mentioned by the writer, is of paramount importance.

The question of selecting upper bend radii and throat dimensions arises. Many considerations enter into this problem. Intentionally avoiding these details, because it was feared they might detract from the original purpose of the paper, the writer selected radii which, in his opinion, gave satisfactory proportions. Mr. Nelidov points out that if a value for r_s of 7.0 is used Equation (4) reads $Q_1 = 39.3\, r_c \log_e \frac{7.0}{r_c}$, and that if the first derivative of Q_1 with respect to r_c is set equal to zero, a value of r_c can be determined which will give a maximum value for Q_1. For the case at hand, this procedure produces throat dimensions of $d = 4.43$ ft and $B = 3.40$, giving a throat area of 15.06 sq ft. Comparison with the throat dimensions of the siphon illustrated in Fig. 2 indicates that the proportions selected by the writer are superior on three counts:

(1) The throat area is considerably smaller, thus decreasing the cost; (2) the priming qualities are better since the length of the crest is greater; and (3) the transition from the rectangular throat to the circular lower leg is easier. The variation of throat dimensions with the upper bend radii can best be represented graphically. In this connection it can be shown that Equation (4), having a given value of r_c inserted, and plotted as a curve (r_c against A_t, in which A_t is equal to Q_{design} × throat depth ÷ Q_1) for a definite siphon capacity, will give smaller throat areas for greater values of r_c, but the throat width (or crest length) will increase rapidly. Obviously there is a practical limit depending upon such considerations as priming qualities, transition in section, and structural requirements.

Perhaps it is well that Mr. Nelidov holds open for discussion the matter of maximum permissible negative pressure. A vacuum head of 24 ft was recommended because it is a reasonable value and has been used in the past with success. It was not the intention of the writer to suggest that hydraulic engineers use the value blindly and without regard for special considerations—for example, operation at extremely high altitudes, or where the quantity of air dissolved in the water is excessive. Each case should be analyzed individually by the designer. If all influencing factors were susceptible to exact analysis it would be perfectly proper to use a vacuum head closer to the maximum of 34 ft. Owing to unforeseen disturbances and unpredictable behavior, the value used should contain a factor of safety. It is common practice in structural design to use a working stress for steel of 16 000 or 18 000 lb per sq in. Actually steel will withstand stresses up to the elastic limit of 32 000 lb per sq in. before it fails. One reason for using the lower stress is to allow for unpredictable secondary stresses.

One method of procedure sometimes resorted to for determining velocity distribution, that has not been discussed, but which warrants mention, is the utilization of the flow net or streamlines. For example, it may be necessary to find the distribution of velocity in the upper leg of a siphon. This can be done by drawing out the streamlines to a large scale.

It is often true in a paper of this nature that there is a tendency on the part of those participating in the discussion to single out certain points and so concentrate their criticism that the broad aspects of the problem as a whole are lost from sight. The writer's aim was to answer certain questions arising in the mind of the engineer confronted with the task of designing a high-head siphon spillway. That atmospheric pressure is a governing force in simple siphonic action is not difficult to understand. On the other hand, the design of a siphon spillway where the operating head is much greater than 34 ft requires a rigorous analysis to be able to guarantee, within practical limits, a fixed capacity and smooth hydraulic performance without vibration and pulsation.

In concluding this discussion the writer wishes to emphasize two points: (1) The assumption of free vortex flow in the upper bend is a valuable aid in designing a siphon; and (2) there is no limit to the operating head for which a siphon can be designed. If the head is greater than 34 ft the only special requirement is that the siphon conduit be formed in such a manner that a break in the water column or its separation from the conduit wall is impossible.

Paper No. 2081

DESIGN OF DOWELS IN TRANSVERSE JOINTS OF CONCRETE PAVEMENTS

By Bengt F. Friberg,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. L. E. Grinter, W. O. Fremont, and Bengt F. Friberg.

Synopsis

Technical literature lacks a rational solution for the deflections and stresses in and around dowels through transverse joints in concrete pavements. The action of the dowel may be established according to general elastic formulas governing for an elastic structure in a yielding mass. These elastic equations are presented herein in simple form and are applied to round dowels such as may be used in road joints under assumed, approximately correct, conditions of yield in the concrete around the dowels. The economical length of dowels is indicated.

A reasonable rule for the rapid appraisal of the effect of dowel spacing is stated and applied to varying dowel spacing. The concrete stress relief furnished by dowels, being a function of dowel deflection and pavement deflection, has been established in practical form based upon the theoretical deflection conditions. The use in design is indicated, and experimental values of stress relief are checked with those obtained with this method of design.

Knowledge of deflections in and around dowels makes it possible to estimate the loads and stresses resulting from inaccurate dowel installation. The values have been developed and applied to experiments of record, giving some indication of the strength of the concrete. The variation in dowel alignment that may be permitted in actual construction, can be gaged to varying joint widths, movements, and dowel sizes.

Present Construction Practice

Transverse joints in concrete pavements are necessary to make longitudinal movements of the pavement possible, and to relieve shrinkage and temperature stresses. In most highway designs round steel dowels are placed across these transverse joints, consisting of $\frac{3}{4}$-in. or $\frac{7}{8}$-in. round plain bars, 2 ft long, spaced

---

Note.—Published in November, 1938, *Proceedings*.

[1] Research Engr., Laclede Steel Co., St. Louis, Mo.

from 12 in. to 20 in. on centers. One end of the dowel is capped and painted or greased to present the least possible resistance to movement of the pavement. The dowels are most frequently in direct contact with the surrounding concrete. In some designs, however, they project into closely fitted heavy sleeves, which, in turn, bear in the concrete. Practical construction considerations, observation of performance, and experimental data rather than design analysis, have led to the construction practices in common use.

The dowels should be required to keep the road surfaces on each side of the joint in alignment even if subgrade support is lacking. They are also required to relieve the concrete stresses due to wheel loads in the immediate vicinity of the joints by transferring a part of these wheel loads to the adjacent pavement. To perform these functions the dowels themselves must be strong enough to carry a reasonable part of load across the joint; and, further, they must be dimensioned so that the bearing pressure between the dowel and the concrete surrounding it does not exceed permissible values. They must transfer their portion of the wheel loads with a sufficiently small deflection to offer a measure of side support to the loaded side of the joint even if the pavement rests on a relatively non-yielding subgrade.

A general mathematical solution of the design problem with specific application to dowels through joints has not appeared in technical literature, although the methods have been referred to by investigators and solutions have been provided for application in specific cases, or under assumed distribution of concrete pressure along the dowel.[2,3] The exact mathematical solution of the problem pertaining to a dowel structure of infinite length has been presented by Professor S. Timoshenko and Mr. J. M. Lessels.[4]

As the deflection of a long dowel in concrete, and the resultant pressure distribution between the dowel and the concrete, are not difficult to establish mathematically, these solutions are presented in the following analysis and from them the dowel performance and dowel effectiveness under common construction conditions have been determined. It has been necessary to use material constants with regard to the deflection of the dowel in the concrete as well as with regard to the deflection of the pavement on the subgrade, which have not been experimentally determined with accuracy. Numerical values included in the paper, therefore, are not intended to be used other than for illustration of the method presented, or with respect to specific experimental evidence.

Notation.—The letter symbols in this paper are defined where they first appear and are arranged, for convenient reference, in the Appendix.

GENERAL SOLUTION

For an elastic structure (see Fig. 1) extending an infinite distance into an elastic mass from its boundary surface, Professor Timoshenko has developed the relationship between the elastic properties of the two structures and the

deflection in the surrounding mass. Fig. 1 is a loading and deflection diagram that illustrates the sign convention adopted.

The relative stiffness of the structure and the mass is expressed by the following constant:

$$\beta = \sqrt[4]{\frac{K\,b}{4\,E_s\,I}} \quad \text{..........................(1)}$$

in which K = a "modulus of support" in an elastic mass, in pounds per inch[3]; b = the width of the structure; E_s = the modulus of elasticity of the structure (28 000 000 lb per sq in.); and I = the moment of inertia of the structure.

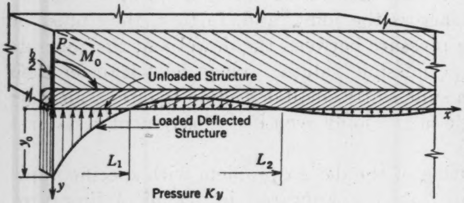

FIG. 1.—LOAD AND DEFLECTION DIAGRAM, SHOWING AN ELASTIC STRUCTURE EMBEDDED IN AN ELASTIC MASS

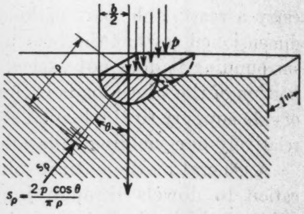

FIG. 2.—DISTRIBUTION OF STRESS IN AN ELASTIC MASS UNDER A DOWEL IF THE CONCRETE ABOVE THE DOWEL IS NEGLECTED

Modulus K is defined as the pressure intensity, in pounds per square inch, on the elastic mass, required to cause a 1-in. settlement. As developed by Professor Timoshenko, the general equation for the deflection, y, of the structure, in the mass, is:

$$y = \frac{e^{-\beta x}}{2\,\beta^3\,E_s\,I}\,\{P\cos\beta\,x - \beta\,M_0\,(\cos\beta\,x - \sin\beta\,x)\} \quad \text{.........(2)}$$

in which e = the base of Naperian logarithms; x = distances from the left end of the structure; P = the concentrated load, in pounds, acting downward at the face of the elastic mass; and M_0 = the bending moment in the structure at the left face of the elastic mass, in inch-pounds. Moment M_0 is positive clockwise. The slope of the structure may be established as the first derivative of Equation (2):

$$\frac{dy}{dx} = \frac{e^{-\beta x}}{2\,\beta^2\,E_s\,I}\,\{(2\,\beta\,M_0 - P)\cos\beta\,x - P\sin\beta\,x\} \quad \text{.........(3)}$$

For x equal to 0, the deflection, y_0, at the face of the mass is:

$$y_0 = \frac{P - \beta\,M_0}{2\,\beta^3\,E_s\,I} \quad \text{..........................(4)}$$

The pressure between the structure and the mass at any point is equal to $K\,y$ and, therefore, is derived directly from the deflection. The points where the pressure on the structure changes from positive to negative are obtained from Equation (2) for $y = 0$; thus:

$$\tan \beta L = 1 - \frac{P}{\beta M_0} \qquad (5)$$

in which L is the distance from the face of the mass to these points. The moment, M, at any point on the structure is obtained directly from Equations (2) and (3):

$$- E_s I \frac{d^2 y}{dx^2} = M = - \frac{e^{-\beta x}}{\beta} \{P \sin \beta x - \beta M_0 (\sin \beta x + \cos \beta x)\} \qquad (6)$$

From this value of M, the shear in the structure, V, at any point may be computed directly:

$$\frac{dM}{dx} = V = - e^{-\beta x} \{(2 \beta M_0 - P) \sin \beta x + P \cos \beta x\} \qquad (7)$$

Application of Design Formulas

The assumption is made that the dowels are not bonded to the concrete and that they fit snugly into the concrete mass. Under these assumptions it is evident that Equations (1) to (7) are directly applicable to long dowels. Load P is equivalent to the shear acting on the dowel, transferred from one road slab to the next. Moment M_0 is the moment in the dowel at the face of the joint incidental to the transfer of this shear. In practice, the dowels are usually not very stiff compared with the concrete pavement. It is an acceptable approximation, then, to presume that a point of contraflexure exists in the dowel at the center of the joint, in which case, for a joint width, a:

$$M_0 = - P \frac{a}{2} \qquad (8)$$

Formulas for the solution of long dowels may then be written in the following simple and usable forms: From Equation (4) the deflection of the dowel with respect to the concrete, at the face of the joint, is:

$$y_0 = \frac{P}{4 \beta^3 E_s I} (2 + \beta a) \qquad (9)$$

From Equation (3) the slope of the dowel at the face of the joint is,

$$\frac{dy_s}{dx} = - \frac{P}{2 \beta^2 E_s I} (1 + \beta a) \qquad (10)$$

From Equation (5) the points, L_n, where the pressure changes direction along the dowel, are:

$$\tan \beta L = \frac{2 + \beta a}{\beta a} \qquad (11)$$

Equation (7), for $\frac{dM}{dx} = 0$, determines the point, x_m, where maximum moment occurs in the dowel:

$$\tan \beta x_m = \frac{1}{1 + \beta a} \qquad (12)$$

By substituting this value in Equation (6), the maximum moment in the dowel is obtained:

$$M_{\max} = -\frac{P e^{-\beta x_m}}{2 \beta} \sqrt{1 + (1 + \beta a)^2} \qquad (13)$$

The stresses and deflections are proportional to P. The locations of the point of maximum moment and of the dowel action, as represented by L_n, are independent of the magnitude of P.

YIELDING OF CONCRETE IN WHICH DOWELS ARE EMBEDDED

Values of K in Equation (1) have not been determined experimentally. The only values known to the writer are those suggested[2, 5] by L. E. Grinter, M. Am. Soc. C. E., of 300 000 lb per in.^{3} and 1 500 000 lb per in.^{3}. K represents the elastic deformation of several inches of concrete above or below the dowel; and its numerical value, therefore, would be less than the modulus of elasticity of the concrete.

The dowels entering a concrete pavement slab are completely surrounded by concrete. The concrete above the dowel holds that immediately beneath the dowel by tension. The compressive stress in the concrete must then be less than the value existing at the dowel in reverse proportion to the depth beneath it. The stress condition illustrated in Fig. 2 is theoretically correct for loadings at a boundary surface. In actual road construction the vertical depth of the concrete beneath the dowel is usually from 3 in. to 6 in., and the vertical pressure in the concrete at the bottom of the slab cannot be greater than the bearing pressure exerted by the slab on the soil. It follows, therefore, that for the average grade of concrete now in use, the value of K probably is higher than 300 000 lb per in.^{3}. In this paper K has been assumed equal to 1 000 000 lb per in.^{3} for all sizes of dowels.

Since the value of K is dependent, to a major degree, upon the pressure immediately at the dowel, its value will probably increase with an increase in the size of dowels; and the experimental establishment of the value, $K b$, is highly desirable. However, since β varies as $K^{\frac{1}{4}}$ (see Equation (1)), a considerable change in K will not influence the stress distribution to any great extent.

DESIGN FORMULAS FOR THE ORDINARY CASE

All the design formulas may be solved directly. Table 1 affords a clear "picture" of the stresses in and around dowels. The maximum moment in the dowels is seen to occur some distance away from the joint, inside the concrete.

For shears other than 1 000 lb, the values of deflections and stresses change in direct proportion for values within the yield point of the steel or the ultimate bearing resistance of the concrete. Stresses above the yield point in the steel

---

[5] *Transactions*, Am. Soc. C. E., Vol. 103 (1938), p. 1157.

(first reached at the point of maximum moment inside the concrete) have the effect of increasing the maximum bearing pressure on the concrete at the face of the joint. Under most construction conditions the bearing stress on the concrete is the critical one. Accordingly, the steel in the dowels should have a sufficiently high yield point so that it is not reached before the bearing stress on the concrete has exceeded any possible ultimate value.

LENGTH OF DOWELS

The foregoing theoretical analysis of dowels, of course, is correct only for an infinitely long dowel. In Fig. 3, the typical diagrams for concrete pressure, dowel shear, and dowel moment have been plotted for an infinitely long 0.75-in. dowel and a joint opening of 1 in. The pressures between the dowel and the concrete decrease very rapidly with each succeeding stress change.

The effect of introducing short dowels can be estimated as a correction factor. The procedure is indicated for 0.75-in. dowels, cut at the second point of pressure change. This point (see Table 1) is 5.81 in. to 5.36 in. from the joint face. According to Equations (6) and (7) the shear and the moment in an infinitely long dowel at this point, for a 0.75-in. dowel and 1-in. joint opening, are: Shear, − 17.5 lb; and moment, + 21.5 in.-lb.

These values are less than 5% of the values at the face of the joint, the moment being of reverse sign. The correction in the actual stresses, made necessary by cutting the dowel at this point, is equivalent to considering the

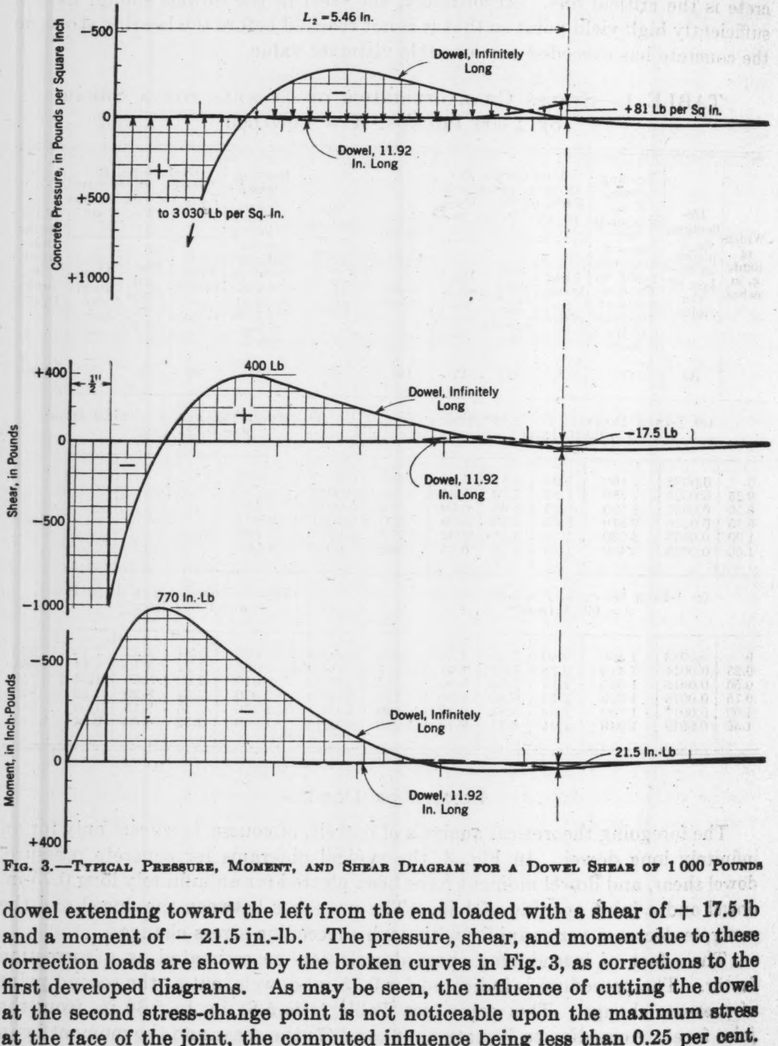

FIG. 3.—TYPICAL PRESSURE, MOMENT, AND SHEAR DIAGRAM FOR A DOWEL SHEAR OF 1 000 POUNDS

dowel extending toward the left from the end loaded with a shear of + 17.5 lb and a moment of − 21.5 in.-lb. The pressure, shear, and moment due to these correction loads are shown by the broken curves in Fig. 3, as corrections to the first developed diagrams. As may be seen, the influence of cutting the dowel at the second stress-change point is not noticeable upon the maximum stress at the face of the joint, the computed influence being less than 0.25 per cent. It is unwarranted to repeat the correction process back from the face of the joint.

The computation indicates that it is entirely unnecessary to extend the dowels beyond the second point of pressure change. Since values of shear and moment are quite low for some distance before the second stress-change point is reached, the dowels could be made as much as 25% shorter without appreciably affecting the maximum stresses in and around the dowels.

DOWEL DEFLECTION ACROSS A JOINT

Of primary importance in judging the dowel action in concrete pavements is the deflection across the joint. The less this deflection, the more nearly will the adjacent pavement slabs match, and thus the greater part of the wheel load will be transferred by the dowel from the loaded side to the unloaded side.

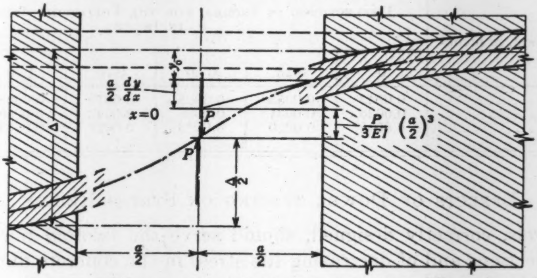

FIG. 4.—DEFLECTION OF A DOWEL ACROSS A PAVEMENT JOINT

For a given shear, the total deflection of a dowel is a function of: (1) The deflection at the faces of a joint; (2) the slope of the dowel, at the faces of the joint; and, (3) the deflection in the part of the dowel in the joint opening. The conditions are illustrated in Fig. 4, and may be defined by a simple formula under the assumption that the faces themselves remain parallel.

The deflection, Δ, across the joint is equal to twice the sum of the following quantities:

(a) The deflection at each joint face, y_0;

(b) The deflection due to the dowel slope over one-half the joint, $\frac{a\,dy_0}{2\,dx}$; and,

(c) The deflection of the dowel steel over one-half the joint, $\frac{P}{3\,E\,I}\left(\frac{a}{2}\right)^3$.

The deflection, Δ, is obtained directly from Equations (9) and (10) by adding Increment (c); that is:

$$\Delta = \frac{P}{2\,E\,I}\left(\frac{1 + (1 + \beta\,a)^2}{\beta^3} + \frac{a^3}{6}\right) \ldots\ldots\ldots\ldots\ldots (14)$$

The deflection is proportional to the dowel shear, P, as shown for 0.75-in., 1-in., and 1.25-in. dowels in Table 2.

In practice, the joint faces would not remain parallel. The slope of the pavement slab in the direction of the dowel, as experimentally observed in tests of the United States Bureau of Public Roads,[6] however, rarely exceeds 10% of the slope of the dowel at the face of the joint as determined by Equation (10). For maximum dowel shear, when the wheel load is near the joint, the two joint faces may slope in opposite directions, minimizing the influence. Therefore, the effect of pavement slope upon dowel deflection across joints may be neglected safely.

TABLE 2.—DEFLECTION ACROSS JOINT FOR 1 000-POUND DOWEL SHEAR AND PARALLEL JOINT FACES

EFFECTS OF DOWEL SPACING ON STRESS RELIEF

The dowels, correctly designed, should serve the twofold purpose of decreasing deflections and of decreasing the stress in the concrete due to concentrated wheel loads. The maximum stress is that which occurs parallel to the edge—for edge-line loading a tensile stress in the bottom of the slab immediately under the load; and, for corner loading, a tensile stress in the top of the slab some distance from the corner. In each case, this stress is proportional to the moment in the concrete and, in turn, to the load supported by the concrete.

Influence of Dowel Spacing Upon Moments.—A dowel placed immediately beneath the load may be assumed to decrease the stress in the pavement in the same proportion as it transfers part of the wheel load to the adjacent slab by the dowel shear. Dowels some distance from the point of loading cannot be considered as effective as those that are closer. They will be farther from the point of maximum moment, and their action will be influenced by shear conditions in the concrete itself. The ideal dowel condition would be that which would transfer shear along the line of the joint identical with the interior of the slab. When support across the joint is lacking, the shear in planes parallel to the joint will increase correspondingly. The combination of shear in the concrete and dowel shear, accordingly, influences the moment and stresses in the concrete.

Convenient diagrams for determining the moment under and near the wheel load have been presented by H. M. Westergaard, M. Am. Soc. C. E.[7] For loadings a considerable distance from any edge the maximum positive moment is beneath the load, the maximum negative moment is $1.8\,l$ from the point of load, l being the radius of relative stiffness as defined by Dean Westergaard. The moment diagrams for loading at an edge a considerable distance from any corner show a small maximum negative moment at approximately the same distance ($1.8\ l$) from the point of loading.

---

[6] "The Structural Design of Concrete Pavements," Pt. 4, *Public Roads*, September, 1936.

[7] "Computation of Stresses in Concrete Roads," by H. M. Westergaard, *Proceedings*, Fifth Annual Meeting, Highway Research Board, 1925.

At the points of maximum negative moment, the shear in the concrete in a plane perpendicular to the edge must equal zero. This shear is the sum of the forces on one side of the section: The subgrade reaction, the concrete shear in planes parallel to the joint, and the dowel shear. Beyond the point, $1.8\ l$, from the load, the moment changes very little. The influence of any one of the shear increments beyond that point, upon moment under the load, therefore, may safely be neglected. The effective dowel shear may reasonably be estimated in accordance with the following rule:

> The effective dowel shear decreases inversely as the distance of the dowel from the point of loading, to zero at a distance of $1.8\ l$. No dowels beyond that point influence the moment at the load point.

It is sufficiently accurate to consider the moment diagram of each dowel shear as identical to that produced by an equal wheel load, the dowel shear acting in an opposite direction to the wheel load. Table 3 gives the moment immediately under the wheel load of effective dowel shears for increasing distances from the point of loading to the dowel, the unit moments being taken directly from data presented by Dean Westergaard.[7]

TABLE 3.—PROPORTION OF EDGE MOMENT RELIEVED BY DOWEL SHEAR

Description	DISTANCE FROM THE LOAD POINT TO THE DOWEL AS A PROPORTION OF THE RADIUS OF RELATIVE STIFFNESS:							
	0	$0.2l$	$0.4l$	$0.6l$	$0.8l$	$1.0l$	$1.4l$	$1.8l$
Proportion of effective dowel shear	1.00	0.89	0.78	0.67	0.55	0.44	0.22	0
Moment at the Load Point, in Inch-Pounds:								
For a unit dowel shear	0.49	0.35	0.15	0.05	0.01	−0.02	−0.05	−0.06
For the effective dowel shear	0.49	0.31	0.12	0.03	0.005	−0.01	−0.01	0
Moment expressed as a proportion of the moment due to one dowel at the load point	1.00	0.64	0.24	0.07	0.01	−0.02	−0.02	0

From these data (Table 3), the relative effectiveness in decreasing slab stress may be developed numerically for any spacing, number, and arrangement of dowels relative to the load point. The sum of the effectiveness of the active dowels, expressed as percentages of the effectiveness of one dowel, immediately beneath the wheel load, for varying pavement depths, and for dowel spacings from 8 in. to 20 in., is illustrated in Fig. 5. The lowest efficiency occurs when the wheel load is between two dowels. With customary dowel spacing, wheel loads between dowels will occur most frequently (see solid lines in Fig. 5), and in rating the stress-relieving value of dowels relative to their spacing, they should be so compared. The average effectiveness for 5-in., 6-in., and 7-in. pavement thickness under these conditions is as follows:

Dowel spacing, in inches	Proportion of single dowel shear
8	1.55
12	1.00
16	0.60
20	0.35

If the dowels are to be effective in decreasing stresses in the concrete, they must be spaced close together.

These values, established directly from Table 3, are based on the assumption that the edge moment distribution is not changed. For very close dowel spacing and for very rigid dowels this assumption would be too approximate and the values must then be corrected for some moment distribution between that for edge loading and for interior loading. The values probably apply closely for dowel spacing of 12 in. with 0.75-in. and 1-in. dowels, and for a spacing of 12 in.; and also for 1.25-in. dowels at expansion joints.

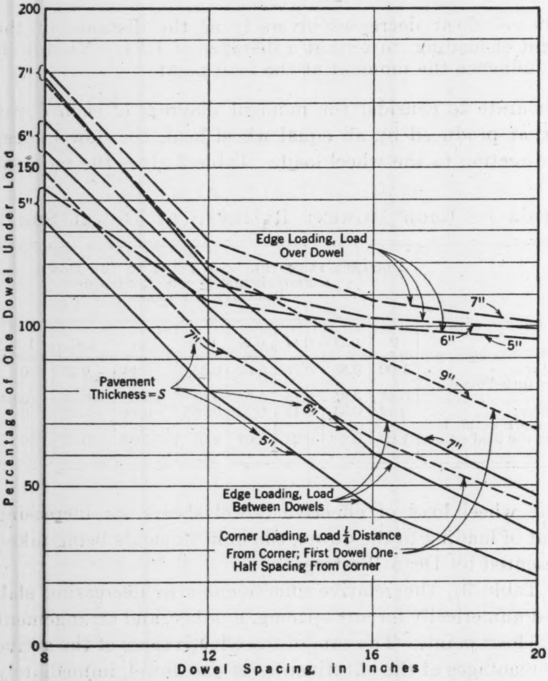

FIG. 5.—TOTAL EDGE STRESS RELIEF AS A PERCENTAGE OF THAT AFFORDED BY ONE DOWEL DIRECTLY UNDER A LOAD

ACTUAL STRESS RELIEF DUE TO DOWELS ACROSS TRANSVERSE JOINTS

Relation Between Pavement Stiffness and Dowel Stiffness.—For a complete evaluation of dowel effectiveness it is necessary to establish a basic value of one dowel at the loading point only. The rates of deflections of dowels have been established as shown in Table 2. The actual load transfer by a dowel directly under the load may then be determined if the deflection of the pavement edges or corners under a load is known.

The assumption that the deflection is directly proportional to the load carried by the concrete (see Fig. 6) approximates closely the results obtained in actual deflection measurements by the Bureau of Public Roads. Computed in accordance with methods established by Dean Westergaard the lines correspond to theoretical values of $k = 300$ for edge loading and $k = 200$ for corner loading.

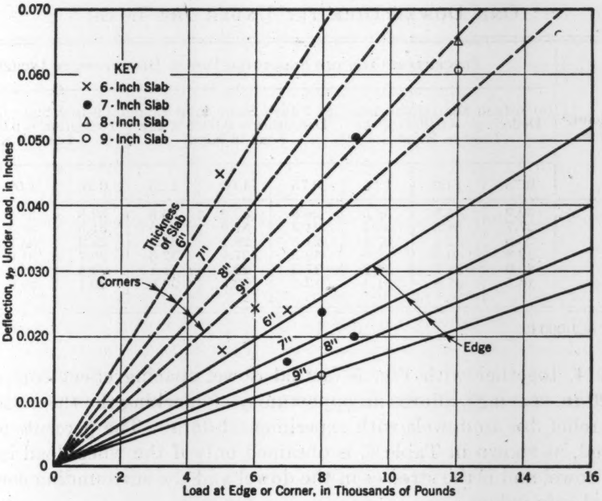

FIG. 6.—DEFLECTIONS OF PAVEMENT UNDER EDGE AND CORNER LOAD ON A SILT LOAM SUBGRADE

The deflection of the loaded pavement edge must equal the deflection of the dowel plus the deflection of the adjacent pavement edge, and the load on the adjacent pavement edge must be the same as the dowel shear. If W = the wheel load, P = the shear on a dowel directly under the load, and y_p and y_d = the deflection of the pavement and the dowel, respectively, for a unit load, the following values govern:

(*a*) The deflection of the loaded edge of a pavement, $y_p (W - P)$;
(*b*) The deflection of the dowel, $y_d P$; and
(*c*) The deflection of the adjacent edge, $y_p P$.

The sum of the deflections on either side must be identical, or:

$$y_p (W - P) = y_d P + y_p P \qquad (15)$$

from which equation the dowel load transfer is obtained, thus:

$$\frac{P}{W} = \frac{1}{2 + \frac{y_d}{y_p}} \qquad (16)$$

The values have been computed for common pavement dimensions in Table 4, with y_p obtained[8] from Fig. 6, and y_d from Table 2.

TABLE 4.—PERCENTAGE OF LOAD TRANSFER ACROSS TRANSVERSE JOINTS FOR PAVEMENTS OF STANDARD THICKNESS; (SILT LOAM SUBGRADE; ONE DOWEL DIRECTLY UNDER THE LOAD)

Table 4, together with Fig. 5 (actual dowel spacing effect computed for 8-in. to 20-in. spacing), affords an opportunity of checking the theoretical value of stress relief due to dowels with experimental data. The percentage of load transferred, as shown in Table 4, is obtained only if the wheel load is directly over the dowel and if the stresses in the dowel and the surrounding concrete do not exceed safe values.

[8] *Public Roads*, October, 1936, p. 176 *et seq.*

Accurate measurements have been reported[8] by L. W. Teller, Assoc. M. Am. Soc. C. E., and Mr. E. C. Sutherland, from which comparative values have been computed in Table 5. The values in Table 5 for a 0.75-in. open joint check closely. For the 7-in. slab with butt-joint, the theoretical values are considerably lower than those developed experimentally, particularly for a wheel load between dowels. These experimental data indicate that there is considerable load transfer and joint restraint due to surface friction across the butt-joint, which will make the experimental values of stress relief greatly higher than what would be obtained with dowels alone.

For open contraction joints and expansion joints of conventional types, the foregoing theoretical method of computing stress relief due to load transfer apparently gives results, in substantial agreement with those observed experimentally. This is evidence that the assumptions in regard to concrete yield, K, and the influence of dowel spacing by the use of edge moment distribution, are fairly correct.

The method offers a possibility of determining the performance of dowels in regard to size and spacing, and to furnishing designs for any required degree of stress relief across a doweled edge. In no applicable case can the load transfer or stress relief exceed 50 per cent. For the close spacing of rigid dowels the method requires adjustment, because in that case it is not a sufficiently close approximation to assume that the moment distribution for an unsupported edge governs for a doweled edge.

STRESSES IN AND AROUND DOWELS

Table 1 gives the concrete bearing stresses around a 0.75-in. dowel for a shear of 1 000 lb. The moment in the dowel for bearing stresses from 2 160 lb per sq in. to 3 460 lb per sq in. varies from 400 in.-lb to 980 in.-lb, and the maximum fiber stress in the dowel varies from 9 700 per sq in. to 23 600 per sq in. Neither of these stresses exceeds that which can easily be taken by the materials; of the two, probably the concrete bearing stress is the critical stress. In joints from 0 in. to 0.75 in. wide and for normal subgrade conditions, 0.75-in. dowels may be expected to transfer not more than about 25% of the wheel load in common pavements as shown in Table 4. A dowel shear of 1 000 lb would then correspond to a single tire load of 4 000 lb. These values are in fair accord with those encountered in actual practice. If the dowels connect pavement slabs under which subgrade support is inadequate, they will be required to transfer more nearly one-half the wheel load, in which case stresses approximately double those for a 1 000-lb dowel shear may be expected to occur. The extreme stresses would then approach both the yield point in the steel and the ultimate compressive strength of the concrete as established by the usual tests, although, in the confined space surrounding the dowel, the ultimate concrete stresses may be considerably higher than those established in the usual tests.

A change from 0.75-in. to 1-in. dowels would improve the load transfer across joints from a 25% to a 33% maximum in accordance with Table 4. The concrete stress beneath the dowel for a 1 000-lb dowel shear would vary from 1 300 to 1 950 lb per sq in., the maximum moment in the dowel from about

495 in.-lb to 1 060 in.-lb, and the extreme fiber stress in the steel from 5 000 to 10 800 lb per sq in. The increased load-transfer capacity would noticeably strengthen the joint edges both against corner cracking and longitudinal cracking between the edge and the center joint. The decrease in stress both in the concrete and in the steel, with the use of 1-in. dowels, is such that their use in heavy-duty concrete pavements seems well warranted.

CONSTRUCTION CONDITIONS AND DOWEL PERFORMANCE

Effect of Inaccurate Dowel Alignment.—If all dowels across a transverse joint are parallel and the concrete slabs remain parallel, there is no resistance to movement in the joint except that exerted by frictional bond between the dowel steel and the concrete. If the dowels are not in alignment, however, their resistance to the movements of the joint will increase in proportion to the severity of the movements. Forces will arise to deflect both the dowels and the pavement edges sufficiently to make their deflection correspond to the relative movement. These are shear forces on the dowels, and their deflection may be computed according to established formulas, as illustrated in Fig. 4. Each one of the two deflections—that of the dowels and that of the pavement—is ascertainable independently. With common dowel spacings, the stiffness of the pavement edge will be so much greater than the stiffness of the dowels that the deflection of the pavement between adjacent dowels may be neglected.

The dowel deflection is given in Equation (14). In its application to a dowel on an angle with the direction of movement, the dowel deflection must equal the transverse component of the movement in a parallel displacement of the dowel; this is proportional to the movement and to the angular deviation of the dowel.

Under the assumption of a fixed pavement edge, the relationship between the deflection of the joint and the dowel misalignment then is:

$$\Delta = \frac{P}{2\,E\,I}\left(\frac{1 + (1 + \beta\, a_i)^2}{\beta^3} + \frac{a_i^3}{6}\right) = \alpha\, i \text{ . . . . } (17)$$

in which i = additional opening of the joint; a_i = new joint width; and α = misalignment of the dowel in the direction of movement, in radians. The relationship between the developed dowel shear, P_s, due to the misalignment, α, therefore, may be written:

$$P_s = \frac{2\,E\,I\,\alpha\, i}{\dfrac{1 + (1 + \beta\, a_i)^2}{\beta^3} + \dfrac{a_i^3}{6}} \text{ . . . . } (18)$$

Table 6 contains computed shear values for various joint widths, and joint movements. The data apply for dowel misalignment in the horizontal as well as in the vertical direction, provided the modulus of support in the concrete, K, is the same in both directions.

With the aid of Table 6, it is possible to find the loads on the dowels for any given construction condition. Shears and bearing stresses are shown for contraction joints and expansion joints in Fig. 7. If the misalignment should be greater than 1% (approximately ⅛ in. per ft of dowel), the dowel deflection necessary for readjustment will be proportionately greater. The resulting dowel loads and stresses will increase proportionately.

Since the bearing stress between the dowel and the concrete apparently is the critical stress, it has been developed from Table 1 and plotted in Fig. 7. As may be seen, exceedingly high concrete stresses accompany excessive dowel misalignment in transverse joints. Dowel loads from this source may exceed those caused by the normal load transfer function.

The actual forces will be less than those developed by assuming that the pavement is entirely rigid. To some extent, the direction of longitudinal movement follows the average alignment of all dowels. The force acting in the dowel, therefore, is dependent on the individual deviation from this average. The full dowel force is not developed if the deviation in alignment occurs gradually from dowel to dowel.

Strength of the Concrete Around the Dowel.—Some general observations of concrete failures around 0.75-in. dowels have been reported by Mr. A. R. Smith and S. W. Benham, Assoc. M. Am. Soc. C. E.[9] The data are classified for study in Table 7, in which the stresses to which the misalignments correspond, as read from Fig. 7, are given in Column (5).

The uniformity of the two sets (in Table 7, Items Nos. 1 and 4 against Items Nos. 2, 3, and 5) of computed stresses for the observed evidence points

to distinctly separate stress conditions in the concrete. The slight spalling, with bearing stresses of about 3 000 lb per sq in., probably indicates failure of a secondary frictional nature, or direct tension immediately beside the dowel. The ultimate stress of more than 10 000 lb per sq in., undoubtedly indicates failure in compression, or for thin pavements failure in tension along the cone-shaped surface under or over the dowel. The behavior, including ten extensive cycles of movement, indicates that it may be safe, in design, to use a bearing stress of somewhat less than 3 000 lb per sq in. between the dowels and the concrete. The data indicate the presence of a high compression stress in the confined concrete surrounding the dowels, which had been expected. Higher stresses under exceptional conditions may be permissible because, although concrete failure would result around an exceptionally faulty dowel, such failure may not be noticeable in a pavement failure on good subgrade.

Permissible Limits of Dowel Misalignment

Theoretical analysis of stresses due to dowel misalignment establishes the fact that the dowels must be placed with considerably greater accuracy for wide joints than for narrow joints if both are to close to the same value of a_i. Fig. 7 also illustrates the fact that 1-in. dowels cause no greater bearing stresses in the concrete than 0.75-in. dowels for identical misalignment. If the limiting stress due to the average misalignment commonly encountered in practice is set at 2 000 lb per sq in. in the concrete, the misalignment of 0.75-in. expansion joints intended to maintain a minimum opening of 0.25 in. should not be more than 1% for either 0.75-in. or 1-in. dowels. The same permissible average dowel misalignment would apply to 0.75-in. or 1-in. dowels extending through a contraction joint with a maximum opening of 0.50 in.

It would seem impossible to tolerate alignment errors of 0.5 in. per ft of length, except under the most exceptional circumstances. The efficiency of the joint and of the dowels is seriously impaired by greater misalignment than $\frac{1}{8}$ in. per ft, although the edges of the joint may not fail.

Practical Problems in Alignment

Most pavement designs include spacer or distribution bars parallel to, and on each side of, transverse joints, to which bars the dowels are tied. The spacer bars are justified for reinforcement at the edge of the joint. However, wiring has not proved adequate to maintain the horizontal alignment of the dowels during the construction operations. Some pavement designs, accordingly, specify crimping or other mechanical processes, to locate the dowels exactly and also to extend the spacer bars exactly to the side forms so the dowels in both pavement lanes are parallel with the longitudinal axis of the pavement. The horizontal alignment can be made exact in that manner without increasing the material or work necessary in the construction of the pavement.

Satisfactory alignment in the vertical direction can be obtained with supports from the subgrade placed near the outer ends of each dowel. These supports must be substantial enough to retain their position during concreting. It should be possible to adjust the dowels with a spirit-level if inspection reveals them to be out of line more than the permissible tolerance. A great number of observations in the field have revealed that, with reasonable care and inspection, dowels supported near their ends may easily be placed with misalignments of less than $\frac{1}{8}$ in. per ft.

Dowels supported on the joints only, or very near the joints, cannot easily be maintained in satisfactory alignment, because they will be influenced by movements of the joint under the action of the fresh concrete. Particular care is required to maintain short dowels in correct alignment as the vertical deviation at their ends is not at once discernible in casual inspection.

CONCLUSION

Dowels across the transverse joints of pavements can be designed exactly by simple formulas. The value of K (1 000 000 lb per in.^{3}) used in this paper should be verified experimentally by actual load tests on dowels. It is believed to be sufficiently close, however, to permit its use for stress determination. Actual stress determinations show relatively high stresses both in and around 0.75-in. dowels under loads that may be encountered in practice. Increase in the size of dowels relieves the concrete stress quickly. The dowel length may be decreased to one-half the 24-in. length now common in actual construction.

Experimental and theoretical stress and moment determinations in pavements subjected to edge loading indicate that dowels which are farther away than 1.8 times the radius of relative stiffness are totally ineffective for the relief of traffic load stresses and that their effect decreases rapidly with increasing distance from the point of load, within the effective distance. Linear decrease in effective shear is proposed as a convenient and sufficient approximation.

Dowel deflection across the joints is primarily a function of dowel deflection and elastic slope at the face of the joint. Deflection of 1-in. dowels is approximately one-half the deflection of 0.75-in. dowels. The stress relief offered by single dowels is dependent on their deflection, and the rate of deflection of the pavement on the subgrade. By proper design and construction, stresses can be reduced 25% to 35% at the average joint opening. Dowels are effective for this purpose if they are spaced sufficiently close. The performance of a dowel can be predicted quickly by the method given in this paper, and the size of the dowel, as well as the proper spacing, can be determined for any desired stress relief. The results check closely the values that have been determined experimentally.

Stresses due to inaccurate dowel installation have been determined. With extreme joint movements, they may exceed the stresses due to traffic loads unless care is given to this construction detail. Observed concrete failures under known conditions of dowel misalignment indicate the presence of high ultimate concrete compression stresses in the confined space around the dowels. A design stress of 2 000 lb per sq in. between the dowel and the concrete appears justifiable. Dowels should be aligned with extreme care if they are to perform their function during the life of the pavement. Satisfactory dowel performance can be obtained with less weight of steel than is now used, but as the dowels are shortened, increasing care must be given the exactness of the supports and spacing of the dowels.

APPENDIX

NOTATION

The following notation conforms essentially with American Standard Symbols for Mechanics, Structural Engineering, and Testing Materials,[10] compiled by a committee of the American Standards Association with Society representation, and approved by the Association in 1932:

a = width of a joint between pavement slabs; a_i = new width after the joint has spread or closed;
b = breadth = the width of a structure embedded in an elastic mass;
E_s = modulus of elasticity of a structure; E_c = modulus of elasticity for concrete;
e = base of Naperian logarithms;
I = moment of inertia of a structure;
i = additional opening or closing of a joint from its original dimension;
K = modulus of support in an elastic mass, defined as the pressure intensity, in pounds per square inch, on a mass, sufficient to cause a settlement of 1 in.;
k = modulus of subgrade reaction;
L = length; $L_1, L_2, \cdots L_n$ = distances to Sections 1, 2, $\cdots$ n, from the face of an elastic mass, Sections 1, 2, $\cdots$ n being points where the pressure changes direction;
l = radius of relative stiffness of the pavement;
M = moment at any point of a structure and an elastic mass; M_0 = moment in a structure at the left face of an elastic mass;
P = load, or shear, on a structure at the face of the elastic mass; P_s = the load equivalent to the developed shear;
s = unit stress; s_ρ = unit stress at radial distance, ρ;
V = shear in the structure at any point;
W = total weight; wheel load;
x = distance parallel to the X-axis, or the horizontal axis of a structure; x_m = point in a dowel where maximum movement occurs;
y = deflection; distances parallel to the Y-axis; deflection of a structure relative to an elastic mass; y_0 = deflection at the face of an elastic mass; y_p = deflection of a pavement acted upon by a unit load; y_d = deflection of a dowel acted upon by a unit load;
α = misalignment of a dowel, in radians;
β = relative stiffness of a structure embedded in an elastic mass;
Δ = total deflection across a joint;
θ = angular distance corresponding to radius of stiffness, ρ;
ρ = radius of stiffness.

---

DISCUSSION

L. E. GRINTER,[11] M. AM. SOC. C. E. (by letter).—The paper by Mr. Friberg presents the second restatement of the general principles of dowel design first presented briefly by the writer as one phase of the structural design of concrete pavements.[12] In 1932 R. D. Bradbury,[3] Assoc. M. Am. Soc. C. E., made use of these same principles to draw other conclusions as to the proper size and spacing of dowels. Since the writer cannot avoid the responsibility of having suggested these approximate methods of analysis to the profession, it seems necessary to point out some of the limitations that should be placed upon the use of such approximations before persons without a proper understanding of the problem reach unacceptable conclusions.

Change in Dowel Practice.—Mr. Friberg states that present practice is to place $\frac{3}{4}$-in. or $\frac{7}{8}$-in. dowels of 2-ft length at from 12-in. to 20-in. centers. When the writer made his study of this problem,[12] a common practice was to use $\frac{1}{2}$-in. or $\frac{5}{8}$-in. dowels at from 3 ft to 5 ft centers. Since that study showed the certain need for heavier dowels at much closer spacing, the trend in present practice is decidedly gratifying; but the trend toward the use of heavier dowels more closely spaced must be carried further and such dowels may need to be made longer than 2 ft for maximum efficiency, as will be demonstrated. This appears in conflict with Mr. Friberg's conclusion that dowels may be shortened to less than 2 ft. Naturally, this lack of agreement is produced by different points of view regarding K, the foundation modulus.

Dowel Deflection Curve.—Based upon mathematically derived formulas that assume perfect elasticity, originally published by Professor S. Timoshenko and Mr. J. M. Lessels,[13] the writer has made the computations of Table 8. In addition to Equation (1), the formulas needed are:

$$y_P = \frac{P\,e^{-\beta x}}{2\,\beta^3\,E\,I}\,(\cos\beta\,x) \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (19a)$$

TABLE 8.—COMPUTATIONS OF RELATIVE DOWEL DEFLECTIONS

and,

$$y_M = \frac{M_0\, e^{-\beta x}}{2\,\beta^2\, E\, I} (\cos \beta\, x - \sin \beta\, x) \;\ldots\ldots\ldots\ldots\ldots (19b)$$

in which y_P is the deflection at any distance, x, along the dowel due to the load, P, applied at its end, and y_M is the corresponding deflection due to an applied end moment, M_0. The constants, E and I, belong to the dowel since the sub-grade factor, K, includes, in its complex make-up, the modulus of deflection of the sub-grade, the modulus of elasticity of the concrete slab, and the stiffness of the slab as measured by its thickness.

The curves of Fig. 8 make several points of importance clear: (1) If moment is neglected, the length of bar producing positive bearing pressure will be one-half the length producing negative bearing pressure; and (2) for resistance to end moment alone, the length of dowel producing positive pressure is decreased 50% but the length of bar to the second point of zero deflection, or of reversed bearing, is not changed greatly. Hence, that length of bar beyond the value of $\beta\, x = 270°$ cannot be very effective in reducing bearing pressure at the joint or under the load. Nevertheless, since dependence is being placed upon a theoretical analysis that actually assumes an infinite length to the bar, it would be the better part of wisdom to design the dowel to project a few inches beyond the point, $\beta\, x = 270°$, or where $x = \frac{1.5\,\pi}{\beta}$.

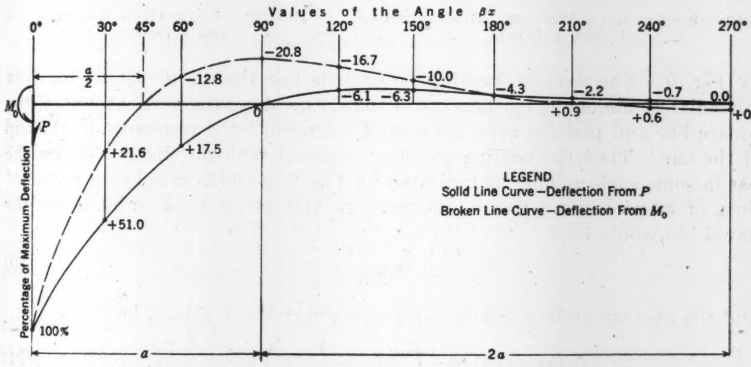

FIG. 8.—COMPARISON OF DOWEL DEFLECTIONS FROM LOAD AND MOMENT

Convenient Computation of Bearing Pressure.—Since both moment and load or shear are applied to the end of the dowel bar at the joint, the use of the length of bar up to the point, $\beta\, x = 0.5\,\pi$, for resistance to positive bearing pressure (with parabolic variation of bearing pressure) is not conservative. In fact, it is definitely liberal. However, it offers a logical procedure for computing dowel-bearing pressure that avoids the direct use of the factor, K (a factor that varies from joint to joint and even from dowel to dowel of the same joint). Fortunately, this factor is under a fourth root radical in the formula for β which means that the required length of the dowel bar is influenced far less directly by the sub-grade modulus than is the bearing pressure.

The Foundation Modulus, K.—Several persons have expressed an interest in the values of 300 000 lb per sq in. and 1 500 000 lb per sq in. that the writer has used on occasion for the factor, K, in Equation (1). This symbol denotes the settlement of the dowel bar, in inches, for a vertical load of 1 lb per sq in. applied to the top surface of the bar. If the dowel bar is supported on a massive foundation, the stress distribution under the bar may be somewhat as indicated

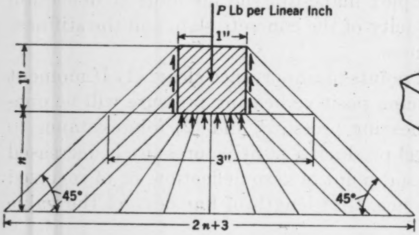

FIG. 9.—POSSIBLE PRESSURE DISTRIBUTION UNDER A DOWEL

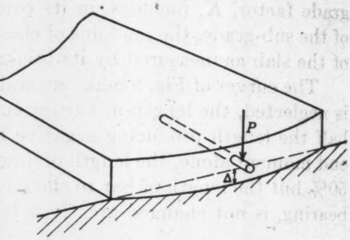

FIG. 10.—FOUNDATION MODULUS FOR A DOWEL

by Fig. 9. The average bearing pressure is less than 1 lb per sq in. even immediately under the bar because of the shears along the vertical sides of the square bar and perhaps even because of a tension bond resistance at the top of the bar. Then the bearing pressure decreases with the distance below the bar in some such manner as indicated by Fig. 9 in which it is based upon 45° lines of distribution. Hence, the average unit stress at n units below the dowel bar would be,

$$f_b = \frac{1}{2\,n + 3} \qquad \text{(20)}$$

and the average vertical compressive stress over the depth, n, becomes:

$$f_b\,(\text{average}) = \frac{1}{2}\left(\frac{1}{3} + \frac{1}{2\,n + 3}\right) = \frac{n + 3}{6\,n + 9} \qquad \text{(21)}$$

For large values of n this fraction becomes nearly $\frac{1}{6}$. Hence, one may write (approximately), $\delta_{1\ \text{lb}} = \frac{n}{6\,E}$, but,

$$K = \frac{1}{\delta_{1\ \text{lb}}} = \frac{6\,E}{n} \qquad \text{(22)}$$

This analysis affords no definite answer to the value of K for the case of a dowel bar projecting from a massive block of concrete; but it does indicate that it may be smaller than E. For instance, if the conditions indicated by Fig. 9 could be expected to hold for a depth of 5 ft below a 1-in. dowel bar set in a massive block of concrete, the value of K would be only 10% of E, or about 300 000 lb per sq in. The writer doubts whether there would be a reduction of this amount but there is another factor to be considered. The tendency, both in practice and in Mr. Friberg's recommendations, is to stress the concrete rather high in bearing under the bar. For stresses above common working stresses the modulus of elasticity of the concrete itself will decrease, and plastic deformation will take place to some degree. This may result in a considerable reduction of K, perhaps even to 300 000 lb per sq in., when the action illustrated by Fig. 9 is also considered. Such a low value, therefore, may be the proper one to use when dowel-bar misalignment in the horizontal plane is studied. Tests are needed to verify this possibility.

Finally, there is the fact that the actual condition to be studied for the case of vertical load transfer by a dowel bar is one for which the dowel is supported by a thin slab which, in turn, rests upon a sub-grade that is expected to re-act nearly elastically for low loads. As shown by Fig. 10, there is not only a compressive deformation in the concrete under the dowel, but the slab actually curves and sinks into the foundation mat. All these factors tend to increase the deflection by a large measure and, of course, they reduce the factor, K.

Assume, for example, that there are 3 in. of concrete below the dowel of Fig. 10. Then, at the soil level, the load might be spread over a width of $2n + 3 = 9$ in. A width of 10 in., however, would still give only a 10 to 1 ratio of the modulus K to the sub-grade modulus itself; for 100 in. the ratio would be 100 to 1. This is far from a satisfactory analysis but it may be somewhat indicative. For a sub-grade modulus of 300 lb per sq in. per in. of settlement (a rather firm material) the correspondingly indicated range of values of K would be from 3 000 to 30 000 lb per sq in. Perhaps the actual value of the foundation modulus is not this low, but nevertheless it calls attention sharply to the fact that present ideas regarding dowel design may have to be revised.

Incidentally, this was the weakness in the theory that the writer had in mind in 1931 when he specified 4-ft dowels.[12] His computations on bearing pressure were made for $K = 300\,000$ lb per sq in., which was regarded as the minimum value that the foundation modulus might approach for a very thick slab or block of concrete. For a thin slab on a soil foundation the modulus, K, was recognized to be subject to a probable serious reduction, and the minimum possible value of perhaps only 3 000 to 30 000 lb per sq in. dictated the specification for 4-ft dowels that was made. In a later publication, in which stresses from misalignment in the horizontal plane were being reported, a value of K of 1 500 000 lb per sq in. was chosen since the purpose was to set limits on the possible disastrous effect of misalignment rather than to study average conditions. Of course, this value was used only for the study of misalignment in the horizontal plane where the soil modulus is not a factor. All this should point out the very indefinite information available regarding the foundation modulus, K, and the need that it should be studied in a scientific manner. The writer believes that this modulus may show a maximum variation of a hundred-fold. Only tests can answer this question.

Longitudinal Warping Produces Severe Dowel Stresses.—A kind of dowel stress that has been given a minimum of consideration by the author, and by all other writers, is the bending produced by longitudinal warping of the pavement. The sub-grade modulus varies from section to section, and temperature variation through the slab is not uniform. The result is that no two undoweled slabs would ever warp in identically the same manner. Hence, there are differences of elevation between the two slabs at the joint that must be equalized by the dowels. The writer has no doubt but that this difference in elevation would amount to $\frac{1}{8}$ in. in a considerable percentage of joints and $\frac{1}{4}$ in., or more, for exceptional cases of non-uniformity. To produce a settlement of $\frac{1}{16}$ in. over an average slab width of only 1 ft near the joint where the sub-grade modulus is 200 (average material) would require a dowel force of $\frac{1}{16} \times 200 \times 144 = 1\,800$ lb per lin ft of joint. (It is assumed that each slab will be displaced $\frac{1}{16}$ in. for a $\frac{1}{8}$-in. differential settlement.) The value of $\frac{1}{16}$ in. chosen is about equal to the upward curling deflection of the slab for a temperature variation of 25° F. It is important to recall that W. K. Hatt,[14] M. Am. Soc. C. E., measured an upward corner deflection of a pavement slab of $\frac{1}{4}$ in. from moisture change only. Hence, it seems reasonable to expect at least $\frac{1}{8}$ in. of differential settlement between adjacent undoweled slabs where lateral curling and longitudinal warping produced by a combination of temperature and moisture changes may readily combine with variations of sub-grade modulus to produce non-uniformity.

The writer's crude estimate of the dowel shear per linear foot of joint as that force necessary to produce a settlement of $\frac{1}{16}$ in. over a slab area 1 ft square can be refined rather easily by taking into account the elastic curve of the slab. Thus, the slab of 20-ft width and 6-in. depth may be considered to be supported on an elastic foundation and loaded at the edge with a series of vertical loads which are the dowel shears from longitudinal warping. Let $K = 200$ lb per sq in. per in. of settlement; then, by Equation (1):

$$\beta = \sqrt[4]{\frac{200 \times 240}{4 \times 3\,000\,000 \times \frac{1}{12} \times 240 \times 6^3}} = 0.031.$$

The length of slab to the second point of zero deflection is defined by $\beta_x = 270° = 1.5\,\pi$; or, $x = \frac{1.5\,\pi}{0.031} = 157$ in. $= 13.1$ ft. For an end deflection of $\frac{1}{16}$ in., $\delta = 0.062 \text{ in.} = \frac{P - \beta\,M_0}{2\,\beta^3\,E\,I} = \frac{P}{2\,\beta^3\,E\,I}$ (nearly); and, $P = 0.062 \times 2 \times 0.031^3 \times 3\,000\,000 \times \frac{1}{12} \times 12 \times 6^3 = 2\,400$ lb, in which P is the dowel load per linear foot of joint. This value indicates that the dowel shear is approximately the load necessary to produce a settlement of $\frac{1}{16}$ in. over a slab area, 1 ft wide by 1 ft 4 in. long, for the particular case studied.

Severe Combinations of Dowel Stress.—In order to evaluate the author's conclusions, it is necessary to determine the possible severity of load combinations. This study will include: (1) A load transfer of 50% of the author's 4 000-lb rear wheel load (which is a smaller load than is permitted in many States); (2) longitudinal warping producing a differential settlement of $\frac{1}{8}$ in. between adjacent undoweled slabs; and (3) misalignment of $\frac{1}{8}$ in. per ft, or $\frac{1}{4}$ in. for a standard length dowel. Calculations will be made for three K-values: A value of 300 000 lb per sq in. as an upper limit with a soft sub-grade; an intermediate value of 30 000 lb per sq in.; and a minimum K-value of 3 000 lb per sq in. Dowels are $\frac{3}{4}$ in. at 12-in. spacing. For $K = 300\,000$, Equation (1) yields $\beta = 0.59$. The required length of dowel would be $2\,(1.5 \times \pi) \div 0.59 = 16$ in. For $K = 30\,000$, $\beta = 0.33$. The corresponding length of dowel would be $2(1.5 \times \pi) \div 0.33 = 29$ in. Finally, for $K = 3\,000$, $\beta = 0.187$. The dowel length then would be $2(1.5 \times \pi) \div 0.187 = 50$ in. Thus, there is the possibility of 4-ft dowels being required, but as a more probable case which is close to present-day practice a study will be made of a dowel of 30-in. length.

---

[14] "The Effect of Moisture on Concrete," by W. K. Hatt, *Public Roads*, March, 1925, p. 15.

The minimum possible bearing stress for a $\frac{3}{4}$-in. dowel, 30 in. long, will occur when positive pressure exists over one-third the length of 10 in. For parabolic variation of pressure and a load transfer of 2 000 lb, the bearing stress is $\frac{3 \times 2\,000}{0.75 \times 10} = 800$ lb per sq in. The corresponding bearing stress for longitudinal warping would be $\frac{3 \times 2\,400}{0.75 \times 10} = 960$ lb per sq in. To this total of 1 760 lb per sq in., which is already as high as any one is willing to recommend, must be added according to the author's estimate another 2 000 lb per sq in. for misalignment, a total of 3 760 lb per sq in. even with 30-in. dowels. Satisfactory functioning of much shorter dowels during the full life of the pavement is obviously questionable.

Conclusion.—The author has presented an interesting study of an old problem. The problem has received less consideration than it deserves because expansion joints, once placed, are not open to inspection until the road is torn up. Failure of road-slabs at other places than the expansion joints have been so frequent that dowel failures have received scant study and little comment. Nevertheless, the crudest possible calculations show rather conclusively that short dowels, widely spaced, are of little value for load transfer and that they subject the concrete to high bearing stresses which reduce, rather early in the life of the pavement, whatever initial effectiveness the dowels may have had.

The author's conclusions are reasonable except in regard to the lengths of dowels. His interpretation of the significance of the factor, K, which must combine in its make-up the sub-grade modulus, the modulus of elasticity of the concrete, and the slab stiffness as measured by its thickness led him to overvalue the significance of his calculations in regard to dowel length. No one can guarantee that the value of K for vertical loading may not be very much lower than the value of 300 000 used by the writer in his first studies of this problem, whereas the author's conclusions are based upon a value of 1 000 000 for K. The result of using a low foundation modulus in the author's calculations might be to revise his conclusions that 24-in. dowels may be shortened to 12 in. and lead to the conclusion that standard 24-in. dowels should be lengthened instead. No one can answer this criticism until adequate tests have been made to set limits upon the foundation modulus, K.

During the interim the only reasonable procedure in analysis is to study each design feature for the corresponding critical value of the sub-grade modulus. Thus, bearing pressure, which controls the diameter and spacing of dowels, must be studied for a relatively high value of the foundation modulus. The dowel length, on the other hand, will be controlled by a relatively low value of the foundation modulus. Even when tests have established the unknown relationships involved, it will still be proper to follow this procedure because the foundation modulus will never be constant for any reasonable length of roadway.

W. O. Fremont,[15] M. Am. Soc. C. E. (by letter).—Under "Present Construction Practice" the author states that the "exact mathematical solution" of the problem pertaining to a dowel structure of infinite length has been presented by Professor Timoshenko and Mr. Lessels. This "exact mathematical" theory is nothing more than a very approximate first tentative approach to the analysis of the actual behavior of a straight elastic bar of uniform rigidity on an elastic foundation. It is simulated roughly by the same bar, continuously connected to an absolutely rigid support by uniformly distributed elastic columns, of constant length and cross-section and constant elastic characteristics (see Fig. 11). It is assumed that each individual column must lengthen or shorten uniformly and independently, without affecting any of the other columns. This assumption implies that at the upper ends the columns are connected with the neutral plane of the bar by means of hinges. At the lower ends they are fixed to the absolutely rigid support. In this way, the bar is assumed to rest on an ideal brush with an absolutely rigid back, and with ideal bristles extending to, and connected with, the neutral plane of the bar by ideal hinges. It is implied: That no shear or friction acts between the bristles; that they do not bend; that they are of very small cross-section; and, that they are spaced close to one another. Let L = the constant length of each column; A_0 = the cross-section area; E = the modulus of elasticity; F_0 = the force in a column that causes lengthening or shortening; ΔL = the change in length of a column under an external load, F_0; N = number of columns per unit area; Σ_p = the sum of the forces in the uniformly stressed columns, referred to a unit area; and, k = modulus of the elastic foundation. Then,

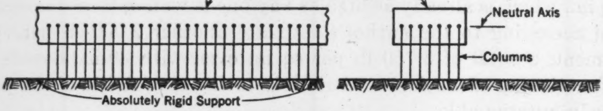

Fig. 11

$$F_0 = \frac{E\,A_0\,\Delta L}{L} \qquad (23a)$$

$$\Sigma_p = N\,F_0 = k\,\Delta L \qquad (23b)$$

$$k = \frac{N\,E\,A_0}{L} \qquad (23c)$$

and, if $N\,A_0 = 1$,

$$k = \frac{E}{L} \qquad (23d)$$

If $E = 4.5 \times 10^6$ lb per sq in. and $L = 4.5$ in., $k = 10^6$ lb-in.$^{-3}$.

The theory based on the foregoing assumptions is also referred to as the elementary theory of beams on elastic foundation. In adapting it to his problem, Mr. Friberg makes a number of assumptions, which the writer proposes to discuss.

---

[15] Bridge Designing Engr., State Highway Dept., Lansing, Mich.

Assumption 1.—The paper is predicated on the principle that the concrete surrounding the dowel behaves as is assumed in the elementary theory of beams on elastic foundations. Conditions similar to this ideal exist only in exceptional cases, if at all, in engineering practice. Nevertheless, the theory based on the foregoing assumption yields satisfactory approximations in some cases. Cases are known in which these approximations are not satisfactory. In dowel construction, the columns may be changed to thin plates of similar characteristics perpendicular to the dowel; and one can visualize easily what will happen when the concrete surrounding the dowel, especially near the ends, is suddenly released from all the shear forces interacting between the plates.

The elementary theory depends upon the assumption that Hooke's law holds. Shear tests on doweled concrete block specimens invariably leave permanent deformations. The first run of the test below the "critical point"[16] may produce a shear-deflection curve that is almost a straight line passing through the zero point for the total, elastic, and permanent deflections. The second run shows a considerable deviation from the straight line especially if the residual deformation of the first run is considered. There are plastic deformations that are not considered by the elementary theory. If the dowel is painted or greased the greater compressibility of the film of paint or grease affects the behavior of the system considerably, especially if the paint is destroyed with the passing of time or by friction between the dowel and the concrete.

It is evident that, by the adoption of the elementary theory for doweled pavement slabs, only a very rough approach to the actual conditions is made and one must be prepared for surprising results when derivations on the basis of this theory are compared with actual observations of construction work or test specimens.

Values of dowel shears in concrete blocks, at the point of failure, computed on the basis of the elementary theory, varied between 4 000 and 14 000 lb (350%) in one set of tests. In the case of dowels of circular cross-section there is a further complication as the distribution of pressures upon the concrete may be different from the one in the case of rectangular prismatic bars.

Assumption 2.—Under "Application of Design Formulas" Mr. Friberg states: "In practice, the dowels are usually not very stiff compared with the concrete pavement. It is an acceptable approximation, then, to presume that a point of contraflexure exists in the dowel at the center of the joint, * * *." By a method similar to the one proposed by Dean Westergaard[17] and, by the introduction of the elementary theory discussed herein under "Assumption 1," the writer has made the following observations:

Load at the joint, in pounds........................	9 000
Thickness of the slab, in inches....................	7
Modulus of elasticity of concrete, in pounds per square inch....................................	4.5×10^6

---

Joint opening, in inches	1
Diameter of dowels, in inches	$\frac{3}{4}$
Spacing of dowels, in inches, center to center	12
Subgrade modulus (bulk modulus of elasticity) in pounds per cubic inch	250
Shear force, T_0, in pounds	920
Moment (see Fig. 12), in inch-pounds, at the:	
Unloaded face, $M =$	− 369
Loaded face, $M_f =$	551
Center, $M_c =$	91
The relative stiffness, $\beta =$	0.793

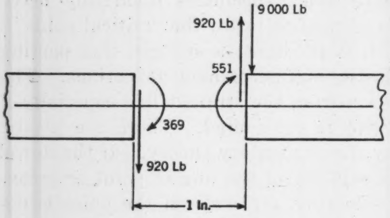

FIG. 12

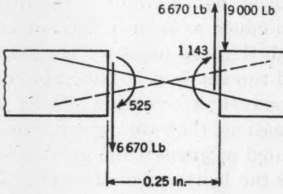

FIG. 13

From the foregoing, the maximum pressure on the concrete, as computed by the formula

$$s = 10^6 \frac{T + \beta M_f}{2 \beta^3 E I} \qquad (24)$$

is $\frac{920}{474} \times 10^3 + \frac{71.3}{474} \times 10^3 + \frac{364}{474} \times 10^3 = 2\,867$ lb per sq in.

Of this pressure, 150 lb per sq in. (that is, 5.25% of the total pressure) is due to the moment $M_c = 91$ in-lb. If the misalignment is uniformly 0.5 in. per foot of dowel, but alternating in opposite direction and symmetric with respect to the load, the condition shown in Fig. 13 was obtained for the center dowel when the opening was decreased to 0.25 in. by expansion. In this case,

$M_c = 6\,670 \times 0.125 - 525 = 308$ in-lb.; and, $s = \frac{6\,670}{474} \times 10^3 + \frac{244}{474} \times 10^3 + \frac{906}{474} \times 10^3 = 14\,100 + 515 + 1\,915 = 16\,530$ lb per sq in., in which 515 is due to M_c and is 3.1% of 16 530.

Assumption 3.—A third assumption involved in the paper is that the foundation modulus of the concrete is assumed to be $k_c = 10^6$ lb per cu in.

Assumption 4.—Under "Design Formulas for the Ordinary Case," the author states: "Under most construction conditions the bearing stress on the concrete is the critical one."

Tests by the writer indicate that the concrete beneath the dowel is subject to strains corresponding to very high compression stresses. According to the mathematical theory of elasticity these stresses must decrease in the direction away from the dowel, and therefore the destruction or plastic deformation of the concrete is limited to a region in the immediate vicinity of the dowel. If the dowel is near the neutral plane of the pavement slab this plastic deformation has no further effect on the slab itself.[18]

It has not been demonstrated that the plastic deformation around the dowel has ever impaired the strength of the pavement slabs directly, but such deformation impairs the load transfer and therefore increases the extreme fiber stresses in the slabs and decreases the strength of the structure indirectly. Therefore, as long as the fiber stresses are under control the pressure of the dowel on the concrete, with any resulting plastic deformation, should not be considered "critical."

Assumption 5.—In the sentence preceding "Dowel Deflection Across a Joint" Mr. Friberg states that, under the conditions cited, the dowels could be made as much as 25% shorter without appreciably affecting the maximum stresses in and around the dowels. If the plastic deformation is taken into consideration, as well as the effects of paint and grease, the points of stress reversal may be found to have moved deeper into the concrete. Furthermore, the use of caps reduces the effective length of the dowels. Therefore, it is necessary to consider, carefully, all the factors affecting the length of the dowels.

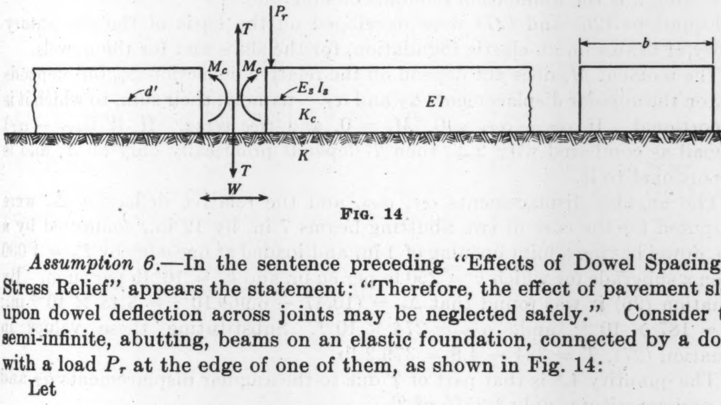

FIG. 14.

Assumption 6.—In the sentence preceding "Effects of Dowel Spacing on Stress Relief" appears the statement: "Therefore, the effect of pavement slope upon dowel deflection across joints may be neglected safely." Consider two semi-infinite, abutting, beams on an elastic foundation, connected by a dowel with a load P_r at the edge of one of them, as shown in Fig. 14:

Let

$$\Delta = 6\,n\,[1 + (1 + \beta\,W)^2] + 6\,m^3\,[1 + (1 + \epsilon\,W)^2] + \beta^3\,W^3 \quad \text{(25a)}$$

$$n = \frac{E_s\,I_s}{E\,I} \quad \text{(25b)}$$

$$\beta = \epsilon\,m = \sqrt[4]{\frac{k\,b}{4\,E\,I}} \quad \text{(25c)}$$

and,

$$\epsilon = \sqrt[4]{\frac{k_c\,d'}{4\,E_s\,I_s}} \quad \text{(25d)}$$

---

[18] "Plasticity," by A. Nadai, McGraw-Hill Book Co., Inc., 1931.

Then,

$$T = \frac{3\,n\,(2 + \beta\,W)}{\Delta}\,P_r \qquad \text{(26a)}$$

and,

$$M_c = \frac{n\,P_r}{2\,\beta\,[2\,(m + n) + \beta\,W]} \qquad \text{(26b)}$$

On the other hand, the static and elastic states of a dowel in a pavement may be defined by the angular displacements α_T and α_{T_r} of the abutting slabs at the faces of the joint and their relative vertical deflection Δ_v, independently of the vertical forces and moments acting on the slabs. Then the bending moment at the center of the dowel will be:

$$M_c = \frac{\epsilon\,E\,I\,(\alpha_T + \alpha_{T_r})}{2 + \beta\,W} \qquad \text{(27a)}$$

and, the shear forces T in the dowel will be:

$$T = \frac{6\,\epsilon^3\,E\,I\,[2\,\Delta_v + W\,(\alpha_{T_r} - \alpha_T)]}{6\,[1 + (1 + \beta\,W)^2] + \beta^3\,W^3} \qquad \text{(27b)}$$

in which d' is the diameter of the dowel; k_c is the foundation modulus of concrete; and, k is the foundation modulus of subgrade.

Equations (26) and (27) were developed on the basis of the elementary theory of beams on an elastic foundation, for the slabs and for the dowels.

The moment M_c does not depend on the relative deflection Δ_v, but depends only on the angular displacements α_T and α_{T_r}—namely, their sum, to which it is proportional. If $\alpha_T + \alpha_{T_r} = 0$, $M_c = 0$, and *vice versa*. If $W\,(\alpha_{T_r} - \alpha_T)$ is small as compared with $2\,\Delta_v$ then T depends practically only on Δ_v and is proportional to it.

The angular displacements α_T, α_{T_r}, and the relative deflection Δ_v were computed for the case of two abutting beams 7 in. by 12 in., connected by a $\frac{3}{4}$-in. dowel having a joint opening of 1 in. and loaded at one edge by $P_r = 1\,000$ lb, on a subgrade for which $k = 250$ lb per cu in. and $k_c = 10^6$ lb per cu in. By Equation (26) it was found that $\Delta_v = (10.47 - 6.96)\,10^{-3} = 3.48 \times 10^{-3}$ in.; $\alpha_T = 187 \times 10^{-6}$; and, $\alpha_{T_r} = 274 \times 10^{-6}$. Substituting these values in Equation (27), $T = 384 - 4.8 = 379.2$ lb.

The quantity 4.8 is that part of T due to the angular displacements α_T and α_{T_r} and constitutes only 1.25% of T.

Assumption 7.—From the Rule stated by the author under "Effects of Dowel Spacing on Stress Relief" it follows that the distribution of shear among the dowels is independent of the elastic characteristics of the joint construction and the amount of joint opening. The reasoning presented in the text preceding the Rule is not convincing and is incomplete. The shear considered near the points of maximum negative moments will be nearly zero only for points near the very edge. For the consideration of equilibrium, including the dowel shear forces, an element of finite dimensions must be considered. For such an element the shears referred to will not be zero on the basis of the reasoning presented in the paper.

For absolutely stiff, or rigid, joint units 50 % of the load will be transferred by one unit at the point of application of the load. For very elastic (say rubber units) the load transfer curve will approach the elastic curve of the loaded slab. In the latter case no load transfer will occur, and almost the entire load will be supported by the loaded slab alone.[19] In the case of dowels in concrete slabs the engineer will be unable even to approach a condition of absolute rigidity in joint construction. The characteristic condition, rather, would tend toward the other extreme.

Assumption 7 calls for a triangular load distribution. In the case of rigid joints there would not be any definable distribution. In the case of very flexible joints the distribution defined by the deflection curve will extend for a distance equal to more than $\pi \times l$ on both sides of the load; at $\pi \times l$ the deflections are still greater than 10% of those under the load.[20]

Field tests on doweled pavements (8-in. slabs, 11 ft wide, loaded on the edge at the center of the pavement, with a 9 000-lb load, 13 dowels of $\frac{3}{4}$-in. diameter, spaced 12 in.) produced edge-deflection curves for the loaded and unloaded edges extending the entire width of the pavement which did not intersect at any point. The relative deflections of the two slabs at the outer edges were still 11% and 15.6% of those under the load.

The radius of relative stiffness was computed as $l = \sqrt{\frac{4.5 \times 10^6 \times 8^3}{12 \times 161}}$ = 33 in. This shows that dowels beyond the point 1.8 l may still have quite a noticeable influence upon the bending moment under the load and the corresponding extreme fiber stresses. The load transfer distribution depends to a great extent on the rigidity of the joint construction.

Assumption 8.—Equation (16) is presented as the expression for defining the shear on a dowel directly under the load. When so defined, P is considered to be quite independent of the dowel spacing and the action of all the other dowels in the joint except the one directly under the load. Consider a pavement construction consisting of two abutting slabs, connected by joint units, on an elastic foundation, with one dowel directly under the load W in Fig. 15.

Equalizing the deflections (Fig. 15):

$$(W - T_0)\, y_p - 2\Delta_T + (M_{0r} - M_0)\, y_m + y_m' - y_m'' = T_0\, y_p + T_0\, y_d \ldots\ldots (28)$$

in which (neglecting the effect of M_0 on y_d):

$$y_m' = a_{11} M_1 + a_{12} M_2 + \cdots \ldots\ldots\ldots\ldots\ldots\ldots (29a)$$

and

$$y_m'' = y_m' + W\,(a_{11} T_1 + a_{12} T_2 + \cdots) \ldots\ldots\ldots\ldots (29b)$$

Substituting Equation (29) in Equation (28):

$$T_0 = \frac{W\, y_p - 2\,\Delta_T + [(M_{0r} - M_0)\, y_m - W\,(a_{11} T_1 + a_{12} T_2 + \cdots)]}{2\, y_p + y_d} \ldots (30)$$

[19] "Joint Testing Experiments with a Theory of Load Transfer Distribution Along the Length of Joints," by J. W. Kushing and W. O. Fremont, *Proceedings*, Fifteenth Annual Meeting, Highway Research Board, December, 1935, p. 154.

[20] "Computation of Stresses in Concrete Roads," by H. M. Westergaard, *Proceedings*, Fifth Annual Meeting, Highway Research Board, December 3–4, 1925, Fig. 9.

Ignoring the influence of the bending moments:

$$\frac{T_0}{W} = \frac{1 - 2\,\dfrac{\Delta_T}{W\,y_p}}{2 + \dfrac{y_d}{y_p}} \ldots \ldots \ldots \ldots \ldots \ldots \ldots (31)$$

in which,

$$\Delta_T = 2\,A_1\,T_1 + 2\,A_2\,T_2 + \cdots \ldots \ldots \ldots \ldots \ldots \ldots (32)$$

is the deflection at Points O and O' produced by the shears T_1, T_2, $\cdots$ alone; and, $W\,y_p$ is the deflection produced at Point O from Load W alone. It is clear

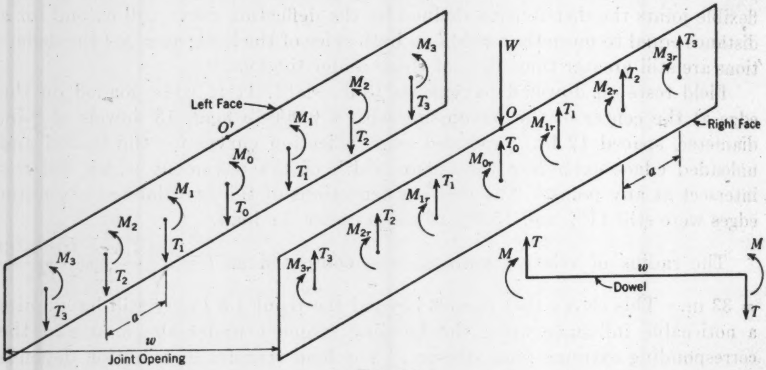

FIG. 15

that the doubled ratio $\dfrac{\Delta_T}{W\,y_p}$ cannot be neglected in Equation (31) without introducing considerable error.

Consider a 7-in. slab with $\frac{3}{4}$-in. dowels. The foundation is elastic, with a foundation modulus of 250 lb per cu in.; the joint is open 1 in.; five dowels are spaced 12 in. apart; and, a load of $W = 9\,000$ lb is concentrated over the center dowel. By a method similar to the one proposed by Dean Westergaard[17] and the introduction of the elementary theory described herein under Assumption 1, the writer has determined the following values: $T_0 = 920$ lb; $T_1 = 673$ lb; $T_2 = 480$ lb; $\Delta_T = 4.086 \times 10^{-6} \times 673 + 330 \times 10^{-6} \times 480 = 4.34 \times 10^{-3}$; $y_p\,W = 2.35 \times 10^{-6} \times 9\,000 = 21.18 \times 10^{-3}$; and (according to Table 2 of the paper), $y_d = 0.0094 \times 10^{-3}$. Consequently, by Equation (31):

$$T_0 = 9\,000\,\frac{1 - 2\,\dfrac{4.34}{21.18}}{2 + \dfrac{94}{23.5}} = 885 \text{ lb},$$

which is not seriously different from the value $T_0 = 920$ lb determined by the writer previously. Equation (16) of the paper yields:

$$T_0 = 9\,000\,\frac{1}{2 + \dfrac{94}{25}} = 1\,562 \text{ lb},$$

an increase of 70%. Mr. Friberg's distribution, as affected by Assumption 7, yields:

$$T_1 = \frac{1.8\,l - a}{1.8\,l}\,T_0 \dots\dots\dots\dots\dots\dots\dots (33a)$$

$$T_2 = \frac{1.8\,l - 2\,a}{1.8\,l}\,T_0 \dots\dots\dots\dots\dots\dots\dots (33b)$$

and

$$T_k = \frac{1.8\,l - k\,a}{1.8\,l}\,T_0 \dots\dots\dots\dots\dots\dots\dots (33c)$$

From Equation (32):

$$\Delta_T = 2\,T_0 \sum_{k=1}^{k=m} \left(1 - \frac{a\,k}{1.8\,l}\right) A_k \dots\dots\dots\dots\dots\dots (34)$$

in which $m + 1 > \frac{1.8\,l}{a} > m$; and, m is an integer. Substituting Equation (34) in Equation (31):

$$\frac{T_0}{W} = \frac{1}{2 + \frac{y_d}{y_p} + 4\,\frac{\sum_{k=1}^{k=m} A_k - \frac{a}{1.8\,l}\sum_{k=1}^{k=m} k\,A_k}{y_p}} \dots\dots\dots\dots (35)$$

in which values of A_k are read from curves presented by Dean Westergaard.[17] In the case of the present numerical example, the conditions stated for Equation (34) are satisfied when $l = 26.8$ in. and $m = 4$. Then: $A_0 = 2.35 \times 10^{-6} = y_p$; $A_1 = 2.043 \times 10^{-6}$; $A_2 = 1.650 \times 10^{-6}$; $A_3 = 1.300 \times 10^{-6}$; $A_4 = 0.935 \times 10^{-6}$; $\sum_{k=1}^{k=4} A_k = 5.928 \times 10^{-6}$; $\sum_{k=1}^{k=4} k\,A_k = 12.983 \times 10^{-6}$; and, $\sum_{k=1}^{k=4} A_k - \frac{12}{1.8\,l}\sum_{k=1}^{k=4} k\,A_k = 2.682 \times 10^{-6}$. Therefore, by Equation (35),

$$T_0 = \frac{9\,000}{2 + \frac{94}{23.5} + 4\,\frac{2.682}{2.35}} = 871 \text{ lb}$$

which checks, reasonably well, the results derived by other methods. Assumption 8, as expressed by Equation (16), should be revised to conform to Equation (35).

The maximum fiber stress at Point O, Fig. 15, may be expressed as

$$s = s_W - s_0 - 2\,s_T \dots\dots\dots\dots\dots\dots\dots (36)$$

in which s_W is the component of stress due to W; s_0 is the component due to T_0; s_T is the component due to T_1, T_2, etc., on one side of the load; and,

$$\gamma_0 = \frac{s_0 + 2\,s_T}{s_0} \dots\dots\dots\dots\dots\dots\dots (37)$$

represents the amount of total stress relief, expressed in the partial relief, produced by the dowel directly under the load as a unit.

Then, the total stress relief at Point O, expressed in terms of the stress s_W, corresponding to the state in which there is no relief (free ledge) as a unit, will be

$$\gamma = \frac{s_0 + 2\,s_T}{s_W} = \frac{s_0}{s_W}\gamma_0 \qquad (38a)$$

Since $s_W = u\,W$; and, $s_0 = u\,T_0$:

$$\gamma = \frac{T_0}{W}\gamma_0 \qquad (38b)$$

and—since $M_0 = m_{0,0}\,T_0$; $M_T = \sum_{k=1}^{k=m} m_{0,k}\,T_k$; $s_0 = \frac{M_0}{W_0}$; and, $s_T = \frac{M_T}{W_0}$—

$$\gamma_0 = 1 + 2\sum_{k=1}^{k=m} \frac{m_{0,k}}{m_{0,0}}\frac{T_k}{T_0} \qquad (38c)$$

in which $m_{0,k}$ are picked from the curves presented by Dean Westergaard.[17]

Formulas similar to Equations (31), (35), (37), (38*b*), and (38*c*) must be derived for the case in which Load W is placed between two dowels.

To compute γ one must know $\frac{T_0}{W}$, Equation (38*b*), in which T_0 is the shear in the dowel directly under the load, with all the other dowels acting according to Assumption 7 and not as assumed by Mr. Friberg in the derivation of Equation (16). For T_0 Mr. Friberg takes the shear in the dowel directly under the load, on the assumption that the other dowels are inactive. Therefore, T_0 in Equation (38*b*) must be determined according to Equation (35). Equation (38*c*) can be computed conveniently by means of graphs.

In introducing Table 3 the author states that the unit moments were taken directly from data presented by Dean Westergaard[7]; and, again, in discussing Fig. 6, he states that the curves were computed in accordance with methods established by Dean Westergaard. The values of y_p may also be obtained from Dean Westergaard's diagrams. Would it not be more logical to use these diagrams throughout the entire analysis, and then compare the theoretical results with experimental measurements, rather than mix theory with experiment?

The percentages of load transfer given in Table 4, the computed values of stress relief in Table 5, and all conclusions drawn on the basis of these tables, need to be adjusted to Equations (35), (38*b*), and (38*c*).

Assumption 9.—The effect of vertical dowel misalignment is determined by Equation (18) on the assumption of uniform alternate misalignment. Under such conditions the maximum fiber stresses in the slab are affected very little. Such ideal conditions of misalignment will occur seldom in actual pavements.

By the same method (with a 7-in. pavement and five dowels spaced at 12 in., the center dowel being misaligned 1 in. per ft of dowel; the original opening was 1 in. and the final was zero), the writer has found: $T_0 = 10\,740$ lb; $T_1 = -3\,380$ lb; and, $T_2 = -2\,025$ lb. The corresponding fiber stresses in the slab were found to be: $s = -10\,740 \times 0.0364 + 6\,760 \times 0.0123 - 4\,050 \times 0.00306$

= − 321.4 lb per sq in. For smaller misalignments this stress will be proportionately smaller, being zero for zero misalignment and − 80.4 lb per sq in. for $\frac{1}{4}$ in. misalignment. The actual misalignment stresses will be smaller owing to the relief afforded by plastic deformation and by the paint or grease effect, which must also be taken into consideration.

The pressure between dowel and concrete is not critical as long as the fiber stresses are under control.

The Nature of Assumptions.—In making assumptions for the simplification of problems in applied mechanics it is important to know the kind and amount of their effect upon the result. Another suggestion is to vary the assumed values so that, by definite variations, a successively closer and closer approach can be made to the exact solution.

Assumptions affecting the laws of mechanics, or conclusions derived from such laws, do not always indicate, directly and clearly, the effect they have upon the results without laborious investigation. Assumptions affecting the characteristics of the materials used are mostly of the same nature (as, for example, the assumption of the linear, or Hooke's, law instead of some curvilinear law). Assumptions affecting the general make-up of the system, without any sacrifice in the exactness of fundamental laws or the characteristics of the materials, often afford a much clearer and easier appraisal of the errors involved by using the approximate solution instead of the exact one. For instance, in the case of a doweled pavement slab construction on an elastic foundation the problem may be simplified by considering only one dowel under the load. It is clear, then, that by introducing three dowels instead of one, the designer approaches closer to the exact solution. With any one of such assumptions (1 or 3 or 5, dowels) he has the advantage of knowing "where he stands"; the road to closer solutions is clear and open and the preceding step helps to make the following one.

Conclusion.—The writer is of the opinion that the method of dowel action analysis introduced by Dean Westergaard,[17] supplemented and extended either by the introduction of the elementary theory of beams on elastic foundation (described herein as Assumption 1) and the consideration of plastic deformation and the effect of grease or paint, or by the use of experimental curves obtained in the laboratory with specimens of actual joint units, is the basic method. On the basis of the data so obtained convenient graphs can be prepared for the use of the practical and field engineer.

Any other methods may be used within definite limits, for definite joint constructions, if their agreement with the basic method has been established within these limits. This is especially important for the analysis of new types of joint construction.

Bengt F. Friberg,[21] **Assoc. M. Am. Soc. C. E.** (by letter).—The purpose of the paper was to present the rules governing the behavior of an elastic structure in a yielding mass in such form that their application to steel dowels, encased in concrete and crossing transverse joints in concrete pavements, would be convenient to the designing engineer. To cover the subject the paper included consideration of dowel spacing as well, although it must be recognized that any analytical evaluation of dowel spacing upon pavement stresses is subject to considerable approximation.

---

[21] Research Engr., Laclede Steel Co., St. Louis, Mo.

Credit for first having indicated the application of bent bars in an elastic foundation to the design of single dowels in concrete pavement joints may be claimed by Dean Grinter.[2] The general solution by Messrs. Timoshenko and Lessels[4] represents the actual conditions around a dowel closer than most other applications; it has been used advantageously in the far less exact structure of railroad tracks. Such approximations as occur are the results rather of non-uniformity in the elastic behavior of the surrounding concrete as evaluated by the modulus of support "K" than in approximations of the solution.

In developing the formulas for dowel design, a number of assumptions were made. Mr. Fremont has enumerated, checked, and substantiated several of these assumptions, and, based on his discussion, the following conditions presented in the paper may be agreed upon as approaching the actual conditions nearly enough for present-day designs:

(*a*) Hooke's law for bearing pressure as proportionate to deflection at any point along a dowel may be applied when contact between the dowel and the concrete exists;

(*b*) Flexible steel dowels of round bars may be assumed to act as hinges between the two slabs with a point of contra-flexure at the center of the joint;

(*c*) Critically high bearing stresses, although sufficient to cause plastic deformation or failure in the concrete around the dowel, need not be considered critical for the pavement;

(*d*) The dowel length in contact with the concrete need not be greater than to the second stress-change point on each side of the joint;

(*e*) Pavement slope at the joint can be neglected in computing the deflection of a dowel across the joint; and

(*f*) Misalignment stresses around the dowels, although critical for the concrete around the dowels, need not be considered critical for the pavement fiber stresses, especially as the largest tension load stresses in the bottom of the pavement edge cannot be added to the largest misalignment stresses. The largest misalignment stresses at the dowels occur when adjacent dowels are misaligned in opposite direction. The largest edge stresses may occur when two or more dowels deviate in the same direction.

The modulus of support of the dowel in the concrete, or, as it will be called, "the modulus of dowel reaction K," has been given a value of 1 000 000 lb per cu in., which is thought to be reasonable for concrete pavements. Dean Grinter has suggested possible K-values in the field as low as from 3 000 to 30 000 lb per cu in. Such a suggestion is based on the assumption that the pavement deflection, as such, is reflected in the factor K. Obviously, that is not the case. The rate at which the concrete around a dowel resists the pressure of the dowel in the concrete does not change with deflection of the body of the concrete. The sub-grade influences the modulus of dowel reaction only to the extent that it permits local deformation of the concrete directly below the dowel and introduces curvature of the pavement slab. The modulus of dowel reaction, therefore, is relatively independent of the material beneath the concrete. Considering the clear relationship between modulus of elasticity of the concrete and the modulus of dowel reaction and customary pavement dimensions, the value of K for reasonable pressures would rarely be less than 25% of the modulus of elasticity.

There is nothing logical in choosing an arbitrary length of dowel embedment and presuming that such a length equals the distance to the second stress-change point, only because such a choice avoids the direct use of the factor K. The value of K is of great influence not only upon the bearing stresses around the dowel, but upon its deflection as well. The relationship between K, deflection, and bearing stress is illustrated in Fig. 16 for a 1-in. open joint, and for dowel sizes from $\frac{3}{4}$ in. to $1\frac{1}{4}$ in. round, deformed. It is evident that the deflection of the dowel for K-values less than 500 000 lb per cu in. quickly becomes so great that the dowels would be considered useless for their basic function of load transfer and would not be used. Fortunately, K would scarcely assume the low values suggested.

Inordinately high values of K would likely result in plastic deformation in the concrete due to the increased bearing stresses. High K-values (which are probably far more common in occurrence) would then be balanced automatically by the increased deflection and decreased load transfer accompanying a dowel of resulting longer free length. The actual bearing stress at the surface of the dowel encased in concrete may be greater than the bearing stress distributed across the diameter of the dowel by as much as 25% (see the rule for radial distribution of bearing stress in Fig. 2).

The estimate of differential warping stresses, by Dean Grinter, indicating a resultant dowel shear of the order of 2 400 lb, does not take into account the fact that the dowel shear due to differential warping would act as a lifting force on one of the slabs, resisted only by the weight of the concrete. Dowel shears considerably less than 1 000 lb for the conditions cited would then be likely to occur. Warping due to moisture differentials would probably raise the two sides of the joint alike. Curling due to temperature differential through the slab would also be likely to cause equal deflection of the two sides of the joint. Warping, therefore, scarcely needs to be considered in the design of dowels. A serious difference in level between adjacent slabs is due, more likely, to the loss of sub-grade support under one of the slabs. High dowel shears of amount equal to, or exceeding, the dowel shears computed for one dowel only according to Equation (16) will then be produced by large wheel loads; but the load-bearing capacity will be limited quickly by the unsupported pavement's resistance to bending stresses.

The effect of dowel spacing upon load transfer and stress relief was presented in the paper with three assumptions to obtain a simple, fairly representative picture, not too tedious for use in actual design. The three assumptions were:

(1) The moment diagram under a dowel load is similar to that under the wheel load;

(2) The influence of dowel shear upon pavement stress decreases with increasing distance from the wheel load to zero at a distance of 1.8 l; and

(3) A dowel directly under the wheel load remains fully effective.

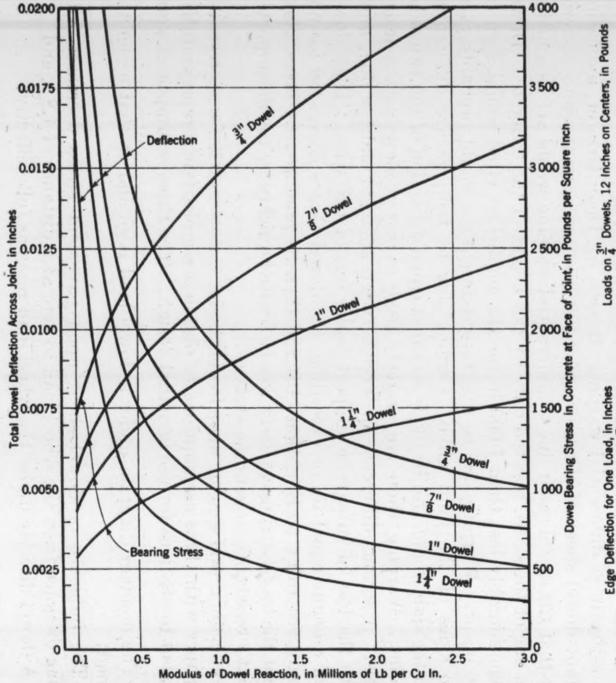

FIG. 16.—DEFLECTION AND BEARING STRESS FOR ROUND DOWELS CROSSING A ONE-INCH JOINT; 1000-POUND DOWEL SHEAR AT VARYING MODULI OF DOWEL REACTION

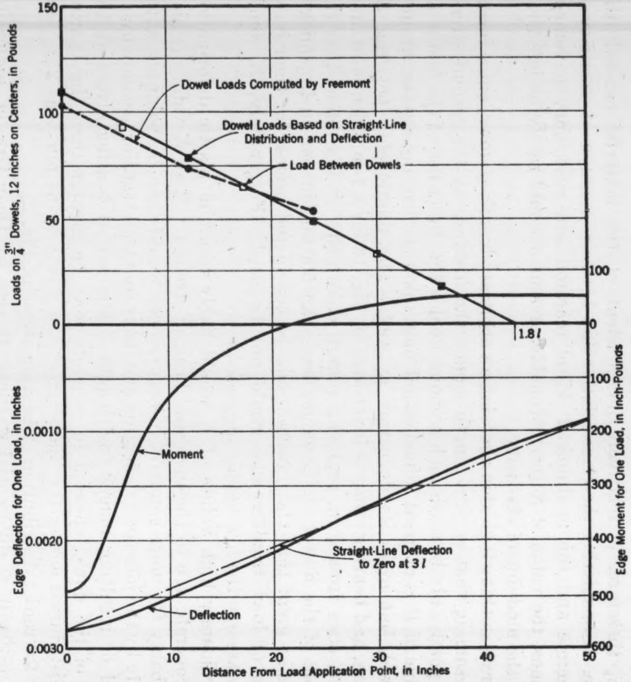

FIG. 17.—DEFLECTION, MOMENT, AND DOWEL LOADS ALONG THE EDGE FOR MODULUS OF SUB-GRADE REACTION 250 POUNDS PER CUBIC INCH; MODULUS OF DOWEL REACTION 1 000 000 POUNDS PER CUBIC INCH; AND RADIUS OF RELATIVE STIFFNESS "l" = 24 INCHES

Mr. Fremont has shown, quite correctly, that with a number of dowels crossing a joint the shear on the dowels nearest the wheel load is decreased. This should relieve high pressures around the dowels, but would also decrease the stress relief furnished by the dowels. Equation (16) is correct for one dowel only. However, even temporary lack of sub-grade support or voids around the dowels would immediately increase the load on the dowels nearest the wheel load. It seems wise to suggest that Equation (16) should be used for dimensioning of the individual dowel when spaced 12 in. or more apart under single tire loads. For the same reason the influence of dowels with sufficient clearance to be free to move, and some distance away from the wheel load where the pavement deflection is correspondingly smaller, would be too small to justify computation of their effect upon pavement stress.

The dowel shears computed by Mr. Fremont for a 7-in. pavement, a sub-grade modulus of 250 ft per cu in., and a 1-in. joint with five $\frac{3}{4}$-in. dowels spaced 12 in. center to center are shown in Fig. 17. Also shown are the moment diagram and the deflection diagram for a single load at the edge. The deflection diagram approximates closely a straight line with zero at a distance of 3.0 l from the load point, a condition typical for edge loadings in accordance with the diagrams developed by Dean Westergaard.[7] The moment quickly diminishes on either side of the load point and reaches a small negative maximum at a distance of about 1.8 l from the load point. Values of distributed dowel shear, based on the straight-line deflection diagram, and on the assumption of linear decrease in dowel loads to zero at a distance of 1.8 l, have been computed by the method described by Dean Westergaard,[17] adjusted to include dowel deflection. These values, plotted for the load over one, and between two, dowels, approach very near to those computed by Mr. Fremont without simplifying assumptions. The illustrated change in computed dowel shear between adjacent dowels is such that for all practical purposes dowels more than 1.8 l distant should be neglected even if the negative moment, maximum at that point, did not suggest that expedient. Therefore, computed values of dowel shear could be used for individual dowel dimensioning under conditions of reliable sub-grade support and accurate construction, especially for dowels on close spacing. The relative edge-stress relief for all dowels at variable dowel spacing, shown in Fig. 5, approximates very closely the actual conditions, expressing as it does the influence of spacing alone. The elastic characteristics of the joint and the joint opening are reflected in the basic value of shear established for a dowel directly under the load.

With the dowel shear distribution computed by Mr. Fremont, the edge-stress relief would be approximately 60% of that obtained under assumption of full effectivity of the dowel directly under the load. The actual edge-stress relief is believed to be considerably higher than that computed from distributed dowel shears. The pavement stress under the load is a function of sub-grade pressure which, in turn, is a function of pavement deflection. Dowels at considerable distance from the load point will be effective in decreasing the deflection, and therefore in affecting the distribution of sub-grade pressure near the load point, although their effect upon stress relief as gaged from the moment diagram would be to add to, rather than relieve, the pavement stress. Higher stress relief may be anticipated also, due to the true position of the dowel reaction at the edge, whereas the maximum edge stress under a wheel crossing a doweled joint occurs while the center of the contact area is some distance from the edge. The greater a concentration of effective dowel shears near the load point is assumed, the greater would be the computed shears on the dowels nearest the load point, and therefore, also, the computed stress relief. How closely the assumption of full effectivity of a dowel directly under the load will be approached with the dowel spacings that are now common remains to be established. For 18-in. dowel spacing the assumption agrees well with observed conditions. For critical comparison of various types of load transfer on different spacings, the relative, and not the absolute, value is sufficient.

The observed stress relief for the 6-in. pavement in Table 5 corresponded to a basic stress relief of 22.8% for one dowel directly under the load. To obtain this value with a computed dowel-shear distribution as presented in Fig. 17 would necessitate a dowel deflection across the joint of only 0.001 in. per 1 000 lb dowel shear, which is less than that obtainable with any possible modulus of dowel reaction for a $\frac{3}{4}$-in. dowel. The observed stress relief accordingly offers further evidence that the dowels nearest the load are more effective than the distributed dowel shears would indicate.

Thanks to the discussion, the value of the paper as an indication of conditions necessary to consider in the design of dowels across transverse joints in concrete pavements has been increased. Due to the uncertain factors upon which the mathematical analysis of a concrete pavement must still be based, it is scarcely recommended that tedious refinements be established for the detail of dowel design. The data give full recognition to the necessity of close dowel spacing for the relief of concrete pavement stresses. Future research may throw added light upon the actual deflection distribution and moments at joints so that the high effectivity of dowels near the load for pavement-stress relief may be substantiated theoretically.

STRESS DISTRIBUTION AROUND A TUNNEL

By Raymond D. Mindlin,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. W. O. Richmond, Jacob Feld, J. H. A. Brahtz, and Raymond D. Mindlin.

Synopsis

The problem of the disturbance of stress around a tunnel is treated in this paper from the point of view of the theory of elasticity. The tunnel is considered to be a horizontal cylindrical hole of circular cross-section situated in a semi-infinite elastic solid under the action of gravity. Through the introduction of the bipolar co-ordinate system an exact solution of the classical elasticity equations is obtained which satisfies the boundary conditions at both the upper free surface of the solid and the free surface of the hole.

Formulas for the stresses are given in terms of infinite series. The series have been evaluated and the results are given in the form of tables and curves which show that the stresses are important when the hole is either very close to the upper surface of the solid or very far from the surface.

Introduction

In the study of the equilibrium of elastic solids, problems are often encountered in which the shape of the structure and the distribution of the loading are so irregular that the ordinary methods of mechanics and strength of materials are not adequate to cope with the situation. The analysis of the disturbance of stress around a tunnel presents just these difficulties. This problem is concerned with an elastic solid of large dimensions, pierced by a hole (the tunnel) and bounded by an unloaded upper surface (Fig. 1). Before this mass is pierced by the tunnel, it is in a condition of elastic equilibrium. The problem considered here is that of the disturbance of this original condition of stress created when the mass is pierced by the tunnel.

The methods of the theory of elasticity have been adapted previously to studies of the tunnel problem.[2] The most nearly complete discussions were

[2] Since this paper was submitted Prof. Z. Anzo has called the author's attention to a paper "On the Stresses in a Gravitating Elastic Body Having a Circular Hole near Its Horizontal Surface," by Z. Anzo (in Japanese), Technology Reports of the Kyushu Imperial University, Vol. XII, No. 3, June, 1937.

given by S. Yamaguti,[3] and H. Schmidt,[4] who investigated the state of stress around a horizontal hole of circular cross-section, situated in a gravitating solid of indefinite extent. In his analysis, Yamaguti correctly considered the effect on the stresses of (1) the weight of the material removed from the hole, and (2) the stress concentration induced by an assumed type of initial stress in the surrounding medium. However, the influence of conditions on the upper surface of the solid was neglected. Accordingly, by St. Venant's Principle, the solution is applicable only when the distance of the hole from the upper surface is large in comparison with the radius of the hole. When such a restriction is made, however, a complicated solution of the type used by Yamaguti is no longer necessary because, in this case, the effect of the weight of the material removed from the hole is negligible in comparison with the stress concentration induced by the initial stress in the surrounding material. When the hole is far from any other boundary the latter effect can be obtained quickly by a method[5] well known in the theory of elasticity. The hole, with its center at point *A* (Fig. 1), is considered simply as situated in a uniform stress field composed of the principal stresses which were initially present at point *A*.

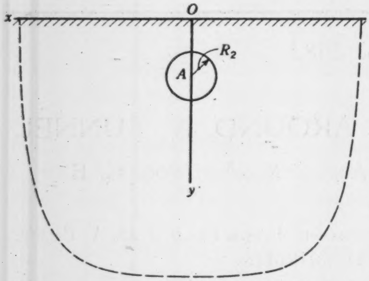

FIG. 1.—HORIZONTAL CYLINDRICAL HOLE OF CIRCULAR CROSS-SECTION IN A GRAVITATING, SEMI-INFINITE, ELASTIC SOLID

An exact solution of the elasticity equations is described here in which full consideration is given to the conditions at both the boundary of the hole and the free upper surface of the solid. The results are valid, therefore, regardless of the proximity of the two boundaries. In fact, the two boundaries may be taken so close together that the solution may be applied to the study of the dead load stresses in the thin-arched structure included between them. A simple method for treating this case is given in Appendix I. Finally, more detailed consideration is given to the assumed state of initial stress in the solid, which need not be the particular state assumed by Yamaguti.

NOTATION

The symbols used in this paper are defined where they first appear and are assembled alphabetically, for reference, in Appendix II.

STATEMENT OF THE PROBLEM

The tunnel is considered to be a horizontal cylindrical cavity of circular cross-section with its axis parallel to the *z*-axis of a rectangular co-ordinate system *x*, *y*, *z*. The surrounding material has, as its upper surface, the plane $y = 0$, but is otherwise unbounded. Technically such a body is known as a semi-infinite solid. The *y*-axis penetrates, in its positive direction, vertically downward and bisects the cross-section of the tunnel (see Fig. 1). The semi-infinite solid has a uniform weight per unit of volume, w, so that the problem involves a constant body force, w, per unit of volume, acting in the positive y direction.

---

[3] "On the Stresses Around a Horizontal Circular Hole in a Gravitating Elastic Solid," by N. Yamaguti, *Journal* of the Civil Engineering Society of Japan, Vol. 15 (1929), pp. 291–303.

[4] "Statische Probleme des Tunnel- und Druckstollenbaues," by H. Schmidt, 1926.

[5] "Theory of Elasticity," by S. Timoshenko, New York, 1934, p. 80.

The length of the tunnel is assumed to be large in comparison with its diameter. This factor and the uniformity of the body force permit a treatment of the problem as one of plane strain.[6]

One method of studying problems in plain strain involves expressing the components of stress in terms of a body-force potential, Ω, and derivatives of a stress function χ. In rectangular co-ordinates these expressions take the form[7]

$$\sigma_x = \frac{\partial^2 \chi}{\partial y^2} + \Omega \dots\dots\dots\dots (1a)$$

$$\sigma_y = \frac{\partial^2 \chi}{\partial x^2} + \Omega \dots\dots\dots\dots (1b)$$

and,

$$\tau_{xy} = - \frac{\partial^2 \chi}{\partial x \, \partial y} \dots\dots\dots\dots (1c)$$

The components (X, Y) of the body force per unit of volume are derived from the body-force potential by

$$X = - \frac{\partial \Omega}{\partial x} \dots\dots (2a); \qquad \text{and,} \qquad Y = - \frac{\partial \Omega}{\partial y} \dots\dots (2b)$$

The stress function χ is a function of x and y only and is governed by the fourth-order differential equation

$$\nabla^4 \chi = - \frac{1 - 2\nu}{1 - \nu} \nabla^2 \Omega \dots\dots\dots\dots (3)$$

in which ν is Poisson's ratio and $\nabla^4 = \nabla^2\nabla^2$ where ∇^2 is Laplace's operator $\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right)$.

In the present case, $X = 0$ and $Y = w$ so that, from Equations (2), $\Omega = - w\,y$; whence $\nabla^2\Omega = 0$ and Equation (3) becomes

$$\nabla^4 \chi = 0 \dots\dots\dots\dots (4)$$

The problem, then, is that of finding a solution of Equation (4) that satisfies a particular set of boundary conditions. The straight boundary and the circular boundary, in this case, are unloaded, and, therefore, there will be four boundary conditions to the effect that the normal stress and the shearing stress on each of these boundaries is zero.

On a horizontal plane, at a great distance below the tunnel, there will be zero shearing stress and a uniform normal stress equal to $- w\,y$. On vertical planes normal to the x-axis and situated at a great distance from the tunnel, the distribution of stress will depend upon the state of stress assumed to have existed in the semi-infinite solid before the boring of the tunnel. Three initial states will be assumed.

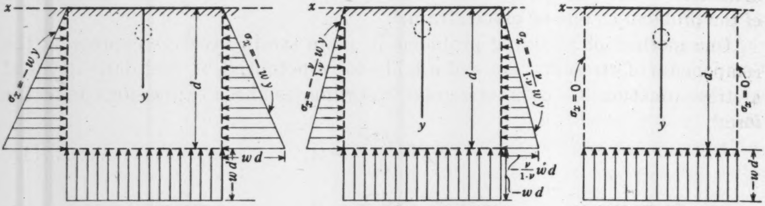
[7] *Loc. cit.*, p. 128.

Case I.—It may be assumed, for example, that each element of the solid is initially under a state of isotropic pressure. The stress in the earth at great depths is probably in this state, approximately. Under this assumption the lateral boundary condition will be a linear distribution of normal pressure $\sigma_x = - w\,y$ as shown in Fig. 2(*a*). Such a stress distribution in the semi-infinite solid, without the hole, may be expressed by means of the body-force potential

$$\Omega = - w\,y \quad (5a)$$

and the stress function

$$\chi_1 = 0 \quad (5b)$$



(*a*) CASE I, HYDROSTATIC PRESSURE

(*b*) CASE II, NO LATERAL DEFORMATION

(*c*) CASE III, NO LATERAL RESTRAINT

FIG. 2.—ASSUMED BOUNDARY CONDITIONS FOR THE SEMI-INFINITE SOLID

Case II.—It might be assumed, however, that initially (long before the boring of the tunnel) the material was restrained from lateral displacement during a supposed application of the gravitational field. In this case it may be shown that the lateral pressure is

$$\sigma_x = - \frac{\nu}{1 - \nu}\, w\,y$$

and that the initial state of stress may be expressed by

$$\Omega = - w\,y \quad (6a)$$

and

$$\chi_2 = \frac{1 - 2\,\nu}{6(1 - \nu)}\, w\,y^3 \quad (6b)$$

This is the state of initial stress (shown in Fig. 2(*b*)) which was assumed by Yamaguti.

Case III.—Another assumption which might be made is that there is no lateral stress at all (Fig. 2(*c*)) in which case the initial stress system may be represented by

$$\Omega = - w\,y \quad (7a)$$

and

$$\chi_3 = \tfrac{1}{6}\, w\,y^3 \quad (7b)$$

These three assumptions include a great range of possibilities for the initial state of stress.

CURVILINEAR CO-ORDINATES

Returning to a consideration of the four boundary conditions on the straight and circular boundaries, it is known that the mathematical form will be greatly simplified if the analysis is framed in a system of curvilinear co-ordinates which is particularly suited to the boundaries. The curvilinear co-ordinate system (α, β) which will be used is obtained through a conformal transformation of the type[8]

$$x + i\,y = f(\alpha + i\,\beta) \dots\dots\dots\dots (8)$$

in which $i = \sqrt{-1}$. Important parts will be taken in the solution by the stretch ratio, J, of the transformation and the angle ϕ which the tangent to the curve $\beta = constant$ makes with the x-axis. It is known[9] that these functions are given by

$$J\,e^{i\phi} = f'(\alpha + i\,\beta) \dots\dots\dots\dots (9)$$

in which e = base of Naperian logarithms. The expressions for the radii of curvature of the co-ordinate curves will be used also. If ρ_1 and ρ_2 are the radii of curvature of $\beta = constant$ and $\alpha = constant$, respectively (both positive for counterclockwise rotation of the tangent moving in the positive direction along the curve), then[9]

$$\frac{1}{\rho_1} = \frac{1}{J}\frac{\partial\phi}{\partial\alpha} = -\frac{1}{J^2}\frac{\partial J}{\partial\beta} \dots\dots\dots\dots (10a)$$

and

$$\frac{1}{\rho_2} = \frac{1}{J}\frac{\partial\phi}{\partial\beta} = \frac{1}{J^2}\frac{\partial J}{\partial\alpha} \dots\dots\dots\dots (10b)$$

Finally, the components of stress in curvilinear co-ordinates are given by[10]

$$\sigma_\alpha = \frac{1}{J^2}\frac{\partial^2\chi}{\partial\beta^2} + \frac{1}{J^3}\left(\frac{\partial\chi}{\partial\alpha}\frac{\partial J}{\partial\alpha} - \frac{\partial\chi}{\partial\beta}\frac{\partial J}{\partial\beta}\right) + \Omega \dots\dots\dots (11a)$$

$$\sigma_\beta = \frac{1}{J^2}\frac{\partial^2\chi}{\partial\alpha^2} + \frac{1}{J^3}\left(\frac{\partial\chi}{\partial\beta}\frac{\partial J}{\partial\beta} - \frac{\partial\chi}{\partial\alpha}\frac{\partial J}{\partial\alpha}\right) + \Omega \dots\dots\dots (11b)$$

and

$$\tau_{\alpha\beta} = -\frac{1}{J^2}\frac{\partial^2\chi}{\partial\alpha\,\partial\beta} + \frac{1}{J^3}\left(\frac{\partial\chi}{\partial\alpha}\frac{\partial J}{\partial\beta} + \frac{\partial\chi}{\partial\beta}\frac{\partial J}{\partial\alpha}\right) \dots\dots\dots (11c)$$

BIPOLAR CO-ORDINATES

A co-ordinate system that is ideally suited to the present requirements is the bipolar system. It was first applied to two-dimensional elasticity by G. B. Jeffery,[11] who gave a general solution of the elasticity equations in this co-ordinate system for the case of zero body force. His method will be adapted to the present requirements after account has been taken of the effect of the action of the gravitational force.

To obtain a system of bipolar co-ordinates, Equation (8) is particularized as

$$x + i\,y = i\,a \coth \tfrac{1}{2}(\alpha + i\,\beta) \dots\dots\dots\dots (12)$$

---

in which a = distance from the origin to a pole, in bipolar co-ordinates. Equating real and imaginary parts in Equation (12) there results

$$x = \frac{a \sin \beta}{\cosh \alpha - \cos \beta} \qquad (13a)$$

and

$$y = \frac{a \sinh \alpha}{\cosh \alpha - \cos \beta} \qquad (13b)$$

From Equations (9) and (12)

$$J\, e^{i\phi} = -\frac{i\,a}{2} \operatorname{csch}^2 \tfrac{1}{2}(\alpha + i\,\beta) \qquad (14)$$

whence

$$J = \frac{a}{\cosh \alpha - \cos \beta} \qquad (15a)$$

and,

$$\tan \phi = \frac{\cosh \alpha \cos \beta - 1}{\sinh \alpha \sin \beta} \qquad (15b)$$

Equation (12) may also be written in the form

$$\alpha + i\,\beta = \log \frac{x + i(y + a)}{x + i(y - a)} \qquad (16)$$

Writing $x + i(y + a) = r_1\, e^{i\theta_1}$ and $x + i(y - a) = r_2\, e^{i\theta_2}$, and equating real and imaginary parts in Equation (16), there results

$$\alpha = \log \frac{r_1}{r_2} \qquad (17a)$$

and

$$\beta = \theta_1 - \theta_2 \qquad (17b)$$

in which r_1 and r_2 are the radii to a point in the x, y-plane from the points $(0, -a)$, $(0, +a)$, respectively, and θ_1, θ_2 are the angles which these radii make with the x-axis, as shown in Fig. 3.

The curves α = *constant* are coaxial circles of radius $a \operatorname{csch} \alpha$ having the poles $(0, -a)$ and $(0, +a)$ as limiting points. The centers of these circles lie on the y-axis at distances $a \coth \alpha$ from the origin. The x-axis is the curve $\alpha = 0$. This and a circle α = *constant* (positive) represent the boundaries of the problem.

The curves β = *constant* are circular arcs passing through the poles $(0, \pm a)$; β is the angle included between the radii r_1 and r_2; it has a discontinuity of 2π on passing between the poles.

In terms of θ_1 and θ_2, the angle ϕ which the tangent to β = *constant* makes with the x-axis is given by

$$\phi = \theta_1 + \theta_2 + \frac{\pi}{2} \qquad (18)$$

From Equations (11) and (15a) the components of stress in bipolar co-ordinates are found to be

$$a\sigma_\alpha = \left\{(\cosh\alpha - \cos\beta)\frac{\partial^2}{\partial\beta^2} - \sinh\alpha\frac{\partial}{\partial\alpha} - \sin\beta\frac{\partial}{\partial\beta} + \cosh\alpha\right\}\left(\frac{\chi}{J}\right) + a\,\Omega \quad (19a)$$

$$a\sigma_\beta = \left\{(\cosh\alpha - \cos\beta)\frac{\partial^2}{\partial\alpha^2} - \sinh\alpha\frac{\partial}{\partial\alpha} - \sin\beta\frac{\partial}{\partial\beta} + \cos\beta\right\}\left(\frac{\chi}{J}\right) + a\,\Omega \quad (19b)$$

and

$$a\tau_{\alpha\beta} = -(\cosh\alpha - \cos\beta)\frac{\partial^2}{\partial\alpha\,\partial\beta}\left(\frac{\chi}{J}\right) \quad (19c)$$

BOUNDARY CONDITIONS

In each of the three cases, there are two curves, α = *constant*, which are free of stress. Since $\tau_{\alpha\beta} = 0$ on a free boundary α = *constant*, Equation (19c) requires that

$$\frac{\partial}{\partial\alpha}\left(\frac{\chi}{J}\right) = \xi \text{ (a constant)} \quad (20)$$

On the same boundary $\sigma_\alpha = 0$. Hence, noting that $-w\,y = -w\,J\sinh\alpha$: and substituting Equation (20) in Equation (19a) with $\sigma_\alpha = 0$, there results,

$$\left\{(\cosh\alpha - \cos\beta)\frac{\partial^2}{\partial\beta^2} - \sin\beta\frac{\partial}{\partial\beta} + \cosh\alpha\right\}\left(\frac{\chi}{J}\right) = w\,a\,J\sinh\alpha + \xi\sinh\alpha \quad\text{..(21)}$$

Equation (21) is an ordinary differential equation the solution of which is found by the usual methods[12] to be

$$\frac{\chi}{J} = \xi\tanh\alpha + \eta\,(\cosh\alpha\cos\beta - 1) + \zeta\sin\beta + w\,a^2\operatorname{csch}\alpha - \tfrac{1}{2}\,w\,a^2\operatorname{csch}^2\alpha\,\phi\sin\beta \quad\text{......(22)}$$

in which ξ, η, and ζ are constants.

Equations (20) and (22) are the conditions which $\frac{\chi}{J}$ must satisfy on each boundary $\alpha = constant$.

The last term in Equation (22) warrants special notice. In the stress function

$$\chi = -\frac{w\,a^2}{2}\operatorname{csch}^2\alpha_1\,\phi\,J\sin\beta \quad\text{......(23)}$$

it is observed that $a \operatorname{csch} \alpha_1$ is the radius, R_2, of the circle $\alpha = \alpha_1$; and that $\phi = \theta_1 + \theta_2 + \frac{\pi}{2}$ and $J\sin\beta = x$. Hence Equation (23) may be written as

$$\chi = -\tfrac{1}{2}\,w\,R_2{}^2\,x\left(\theta_1 + \theta_2 + \frac{\pi}{2}\right) \quad\text{......(24)}$$

Equation (24) is recognized as the stress function for a pair of single forces[13] acting at the poles in the direction of the negative y-axis. The magnitudes of the forces are equal to $w\,\pi\,R_2{}^2$ which is the weight per unit of thickness of the material included in the circle $\alpha = \alpha_1$. Hence Equation (23) is the stress function required to annul the resultant of the stresses produced on $\alpha = constant$ by the body force.

EARLY TERMS OF THE STRESS FUNCTION

In order to satisfy the boundary conditions on a boundary $\alpha = constant$, the following procedure suggested by Jeffery[11] will be followed. The resultant of whatever stresses exist on the boundary will be annulled first and then a general method, due to Jeffery, will be applied to eliminate the remaining stresses.

It was seen in the preceding section that the resultant of the stresses on a boundary $\alpha = \alpha_1$ may be removed by the stress function given in Equation (23). This function introduces many valued terms[14] in the displacements. In the present problem it is required that the displacements be single-valued in the region $\alpha > 0$. This may be accomplished by adding the stress function

$$\frac{\chi}{J} = \frac{1 - 2\nu}{4\,(1 - \nu)}\,a^2\operatorname{csch}^2\alpha_1\left[\alpha\sinh\alpha - \alpha\,(\cosh\alpha - \cos\beta)\right] \quad\text{....(25)}$$

---

[12] "Differential Equations," by H. T. H. Piaggio, London (1929), Chapter VII.

[13] "A Treatise on Photo-Elasticity," by E. G. Coker and L. N. G. Filon, Cambridge, University Press, 1931, p. 327.

[14] "A Treatise on Photo-Elasticity," by E. G. Coker and L. N. G. Filon, Cambridge, University Press, 1931, p. 326.

Equation (25) is perhaps more readily recognized when it is written in terms of r_1, r_2, θ_1, θ_2:

$$\chi = \frac{1 - 2\,\nu}{4\,(1 - \nu)}\, w\, R_2^2\, [(y - a) \log r_2 - (y - a) \log r_1] \ldots\ldots (26)$$

The term $(y - a) \log r_2$ in Equation (26) serves to eliminate the many-valued displacements in the region $\alpha > 0$ which were introduced by the term $x\,\theta_2$ in Equation (24).[13] Accordingly there should be included, in the stress function, the early terms

$$\frac{\chi_4}{J} = -\tfrac{1}{2}\, w\, a^2 \operatorname{csch}^2 \alpha_1$$

$$\times \left\{ \phi \sin \beta - \frac{1 - 2\,\nu}{2\,(1 - \nu)} [\alpha \sinh \alpha - \alpha (\cosh \alpha - \cos \beta)] \right\} \ldots . (27)$$

First Auxiliary Stress Function

The stress function χ_4 leaves only a self equilibrating system of stress on $\alpha = \alpha_1$; but, at the same time, it introduces stresses on the initially free boundary $\alpha = 0$. It is advantageous to remove the stresses introduced on $\alpha = 0$ by Equation (27) before proceeding with the application of the boundary conditions, Equations (20) and (22). In this way advantage may be taken of a great simplification of the boundary equations suggested by Jeffery.

The stress function required to annul the stresses produced on $\alpha = 0$ by Equation (27) is well known.[15] In terms of the bipolar notation it is:

$$\frac{\chi_5}{J} = \frac{w\, a^2}{8\,(1 - \nu)} \operatorname{csch}^2 \alpha_1 (\cosh 2\,\alpha - \sinh 2\,\alpha - 1) \cos \beta \ldots\ldots (28)$$

It should be observed that Equations (27) and (28), combined, represent the two-dimensional solution for a force of magnitude $w\,\pi\,R_2^2$ applied along the y-axis at Point $(0, a)$ in the interior of the semi-infinite solid $y > 0$.

Second Auxiliary Stress Function

It is now required to find a second auxiliary stress function, satisfying Equation (4), which will annul the stresses on $\alpha = \alpha_1$ introduced by $\chi_{1,2,3}$, χ_4, χ_5 and Ω, and at the same time produce no stresses on $\alpha = 0$. In curvilinear co-ordinates Equation (4) becomes[16]

$$\left(\frac{\partial^2}{\partial \alpha^2} + \frac{\partial^2}{\partial \beta^2}\right)\left\{\frac{1}{J^2}\left(\frac{\partial^2 \chi}{\partial \alpha^2} + \frac{\partial^2 \chi}{\partial \beta^2}\right)\right\} = 0 \ldots\ldots\ldots\ldots (29a)$$

Jeffery showed that, for the case of bipolar co-ordinates, Equation (29a) can be reduced to a linear equation with constant coefficients by considering $\frac{\chi}{J}$

---

[15] "Der Spannungszustand der durch eine Einzelkraft im Innern beanspruchten Halbscheibe," by E. Melan, *Zeitschrift für Angewandte Mathematik und Mechanik*, Vol. 12 (1932), pp. 343–346; see also "Stress Systems in a Circular Disk under Radial Forces," by R. D. Mindlin, *Transactions*, A. S. M. E., Vol. 59 (1937), pp. A-115 to A-118; and "Force at a Point in the Interior of a Semi-Infinite Solid," by R. D. Mindlin, *Physics*, Vol. 7 (1936), pp. 195–202.

[16] "A Treatise on Photo-Elasticity," by E. G. Coker and L. N. G. Filon, Cambridge, University Press, 1931, p. 164.

instead of χ as the dependent variable. Equation (29*a*) then becomes

$$\left(\frac{\partial^4}{\partial\alpha^4} + 2\,\frac{\partial^4}{\partial\alpha^2\,\partial\beta^2} + \frac{\partial^4}{\partial\beta^4} - 2\,\frac{\partial^2}{\partial\alpha^2} + 2\,\frac{\partial^2}{\partial\beta^2} + 1\right)\left(\frac{\chi}{J}\right) = 0 \;\ldots\ldots (29b)$$

On account of the symmetry of the present problem, the solution must be even in β. Furthermore, since there is a discontinuity of $2\,\pi$ in β on passing between the poles, the solution must be periodic in β, of period $2\,\pi$. A solution of the form

$$\frac{\chi_6}{J} = f\,(\alpha)\cos n\,\beta \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

will therefore be considered. Substituting Equation (30) in Equation (29*b*) there results:

$$\left(\frac{d^4}{d\alpha^4} - 2\,(n^2 - 1)\,\frac{d^2}{d\alpha^2} + n^4 - 2\,n^2 + 1\right) f\,(\alpha) = 0 \ldots\ldots (31)$$

Equation (31) is an ordinary differential equation whose solution is found to be, by the usual methods:[17a]

For $n \geqq 2$,

$$f_n\,(\alpha) = A_n \cosh\,(n+1)\,\alpha + B_n \cosh\,(n-1)\,\alpha$$
$$+ \; C_n \sinh\,(n+1)\,\alpha + D_n \sinh\,(n-1)\,\alpha \ldots\ldots\ldots\ldots (32a)$$

for $n = 1$,

$$f_1\,(\alpha) = A_1 \cosh 2\,\alpha + B_1 + C_1 \sinh 2\,\alpha + D_1\,\alpha \ldots\ldots\ldots (32b)$$

and, for $n = 0$,

$$f_0\,(\alpha) = A_0 \cosh\alpha + B_0\,\alpha\cosh\alpha + C_0 \sinh\alpha + D_0\,\alpha\sinh\alpha \ldots\ldots (32c)$$

Now, $A_0 \cosh\alpha$ and $B_1 \cos\beta$ give the same stresses; hence, A_0 may be taken equal to zero, which is equivalent to adding a constant term to the stress function. An inspection of Equations (20) and (22), with $w = 0$, reveals that χ_6 will produce no stresses on $\alpha = 0$, if

$$f\,(0) = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (33a)$$

and

$$f'\,(0) = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (33b)$$

Substituting Equations (32) in Equations (33), the following relations are obtained among the constants, which will assure the vanishing of σ_α and $\tau_{\alpha\beta}$ when $\alpha = 0$:

For $n \geqq 1$,

$$A_n + B_n = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (34a)$$

for $n \geqq 2$,

$$(n+1)\,C_n + (n-1)\,D_n = 0 \ldots\ldots\ldots\ldots\ldots (34b)$$

Also

$$2\,C_1 + D_1 = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (34c)$$

and,

$$B_0 + C_0 = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (34d)$$

Jeffery has shown that the condition that the displacements be single valued requires that

$$D_0 = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (35a)$$

[17a] "Differential Equations," by H. T. H. Piaggio, London (1929), Chapter III.

and

$$D_1 + B_0 = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (35b)$$

Substituting Equations (34) and (35) in Equations (32) and writing E_n for $\frac{C_n}{(n-1)}$, the following form is found for the second auxiliary stress function:

$$\frac{\chi_6}{J} = B_0 \left[\alpha (\cosh \alpha - \cos \beta) + \sinh \alpha (\cosh \alpha \cos \beta - 1)\right]$$

$$+ A_1 (\cosh 2\alpha - 1) \cos \beta + \sum_{n=2}^{\infty} \{A_n \left[\cosh (n+1) \alpha - \cosh (n-1) \alpha\right]$$

$$+ E_n \left[(n-1) \sinh (n+1) \alpha - (n+1) \sinh (n-1) \alpha\right]\} \cos n \beta \ldots (36)$$

(The line of reasoning leading from Equations (33) to (36) is essentially that followed by Jeffery[11] in applying his general bipolar solution to the problem of a semi-infinite plate containing an unstressed circular hole, and under a uniform tension parallel to its straight edge. The process has been repeated here because Jeffery considered correctly only the first of the conditions given in Equations (34), with the result that the term $B_0 \sinh \alpha (\cosh \alpha \cos \beta - 1)$ is lacking in his Equation (66).[11] Consequently, in his application, the boundary conditions on $\alpha = 0$ are not satisfied.)

COMPLETE STRESS FUNCTION

The complete stress function (χ) is the sum of the initial stress function (χ_1, χ_2, or χ_3), the early terms (χ_4) and the two auxiliary stress functions (χ_5 and χ_6), as follows:

$$\frac{\chi}{J} = \frac{\chi_{1,2,3}}{J} - \frac{w a^2}{2} \operatorname{csch}^2 \alpha_1$$

$$\times \left\{ \phi \sin \beta - \frac{1 - 2\nu}{2(1-\nu)} \left[\alpha \sinh \alpha - \alpha (\cosh \alpha - \cos \beta)\right] \right\}$$

$$+ \frac{1}{8(1-\nu)} w a^2 \operatorname{csch}^2 \alpha_1 (\cosh 2\alpha - \sinh 2\alpha - 1) \cos \beta$$

$$+ B_0 \left[\alpha (\cosh \alpha - \cos \beta) + \sinh \alpha (\cosh \alpha \cos \beta - 1)\right]$$

$$+ A_1 (\cosh 2\alpha - 1) \cos \beta + \sum_{n=2}^{\infty} \left\{ A_n \left[\cosh (n+1) \alpha - \cosh (n-1) \alpha\right]\right.$$

$$\left. + E_n \left[(n-1) \sinh (n+1) \alpha - (n+1) \sinh (n-1) \alpha\right] \right\} \cos n \beta \ldots (37)$$

There remains only the determination of the arbitrary constants. This is accomplished by substituting Equation (37) in Equations (20) and (22) with the proper value for $\chi_{1,2,3}$ for each of Cases I, II, and III.

CASE I

In this case the first term on the right in Equation (37) is $\frac{\chi_1}{J} = 0$. The determination of the constants B_0, A_1, A_n, E_n by substitution of Equation (37) in the boundary conditions (Equations (20) and (22)) is perfectly straightforward except for one consideration. The difficulty arises from the appearance of a term $\frac{\sin^2 \beta}{(\cosh \alpha_1 - \cos \beta)}$ which results from the differentiation of the function $\phi \sin \beta$ with respect to α in Equation (20).

The values of the constants are determined by solving a set of simultaneous linear equations formed by equating coefficients of like terms of the type $\cos n\beta$. The term involving $(\cosh\alpha_1 - \cos\beta)$ in the denominator can only be adapted to this process by expanding it in infinite series as follows:

$$\frac{\sin^2\beta}{\cosh\alpha_1 - \cos\beta} = e^{-\alpha_1} + e^{-2\alpha_1} - 2\sinh\alpha_1 \sum_{n=2}^{\infty} e^{-n\alpha_1}\cos n\beta \ldots\ldots (38)$$

This is valid for $\alpha_1 > 0$. It is the appearance of this term in the first boundary condition which necessitates an infinite series solution. Were it not for this term the constants A_n and E_n would vanish and the final stress function would appear as the sum of a finite number of elementary functions.

Using Equation (38) after the substitution of Equation (37) in Equations (20) and (22), the following values for the constants result:

$$B_0 = -\tfrac{1}{2}\, w\, a^2 \operatorname{csch}^2\alpha_1 \left[2\coth\alpha_1 + \frac{1-2\nu}{2(1-\nu)}(\coth\alpha_1 - 1)\right] \ldots (39a)$$

$$A_1 = \tfrac{1}{2}\, w\, a^2 \operatorname{csch}^2\alpha_1 \ldots\ldots\ldots\ldots (39b)$$

$$A_n = -\tfrac{1}{2}\, w\, a^2 \operatorname{csch}^2\alpha_1$$

$$\times \frac{e^{-n\alpha_1}\sinh\alpha_1(\sinh n\alpha_1 \cosh\alpha_1 - n\cosh n\alpha_1 \sinh\alpha_1)}{\sinh^2 n\alpha_1 - n^2\sinh^2\alpha_1} \ldots\ldots (39c)$$

and

$$E_n = -\tfrac{1}{2}\, w\, a^2 \operatorname{csch}^2\alpha_1 \frac{e^{-n\alpha_1}\sinh^2\alpha_1 \sinh n\alpha_1}{\sinh^2 n\alpha_1 - n^2\sinh^2\alpha_1} \ldots\ldots\ldots (39d)$$

Substituting Equations (39) in Equation (37), the stress function for Case I is found to be:

$$\begin{aligned}\frac{\chi}{J} = -\tfrac{1}{2}\, w\, a^2 \operatorname{csch}^2\alpha_1 \Bigg\{ & \phi\sin\beta - \frac{1-2\nu}{2(1-\nu)}\alpha\sinh\alpha \\ & + \frac{5-6\nu}{2(1-\nu)}\coth\alpha_1(\cosh\alpha - \cos\beta)\alpha - \frac{3-4\nu}{4(1-\nu)}(\cosh 2\alpha - 1)\cos\beta \\ & + \frac{1}{2}\left(\frac{5-6\nu}{2(1-\nu)}\coth\alpha_1 - 1\right)\sinh 2\alpha\cos\beta + \sum_{n=2}^{\infty}\frac{2\sinh\alpha_1 e^{-n\alpha_1}}{\sinh^2 n\alpha_1 - n^2\sinh^2\alpha_1} \\ & \times [\sinh n\alpha_1 \sinh n\alpha \sinh(\alpha - \alpha_1) \\ & - n\sinh\alpha_1 \sinh\alpha \sinh n(\alpha - \alpha_1)]\Bigg\}\cos n\beta \ldots\ldots\ldots\ldots (40)\end{aligned}$$

The most important stresses are those in the circular boundary. Using Equations (19b) and (40):

$$\begin{aligned}[\sigma_\beta]_{\alpha=\alpha_1} = \frac{w\, a(\cosh\alpha_1 - \cos\beta)}{2\sinh^2\alpha_1}\Bigg\{ & \frac{2(1-\cosh\alpha_1\cos\beta)\sinh\alpha_1}{(\cosh\alpha_1 - \cos\beta)^2} \\ & - 4\cosh\alpha_1 - \left(\frac{5-6\nu}{1-\nu} + 2e^{-2\alpha_1}\right)\cos\beta \\ & - 4\sinh\alpha_1 \sum_{n=2}^{\infty} N_n \cos n\beta\Bigg\} \ldots\ldots\ldots\ldots (41)\end{aligned}$$

in which

$$N_n = \frac{n\, e^{-n\alpha_1} (\sinh n\, \alpha_1 \cosh n\, \alpha_1 - n \sinh \alpha_1 \cosh \alpha_1)}{\sinh^2 n\, \alpha_1 - n^2 \sinh^2 \alpha_1} \ldots\ldots (42)$$

In order to obtain numerical values for $[\sigma_\beta]_{\alpha=\alpha_1}$ it is necessary to tabulate values for the series in Equation (41); but it is found that the series converges very slowly, especially for small values of α_1. To facilitate the computations, the more slowly converging part may be separated by letting

$$N_n = n\, e^{-n\alpha_1} + R_n \ldots\ldots (43)$$

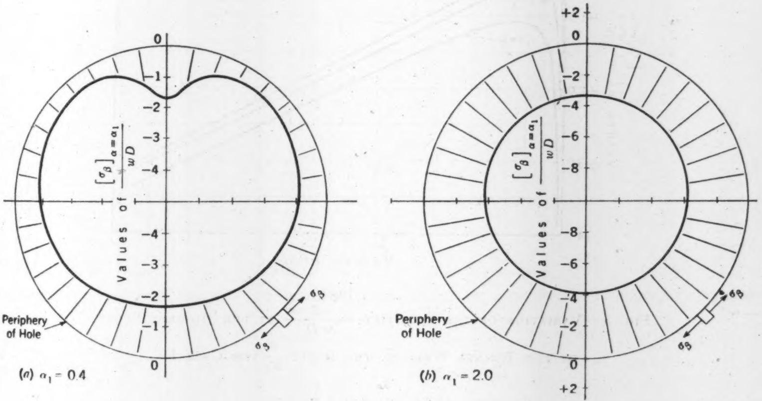
Noting that

$$2 \sum_{n=1}^{\infty} n\, e^{-n\alpha_1} \cos n\, \beta = \frac{\cosh \alpha_1 \cos \beta - 1}{(\cosh \alpha_1 - \cos \beta)^2} \ldots\ldots (44)$$

and substituting Equation (43) in Equation (41):

$$[\sigma_\beta]_{\alpha=\alpha_1} = \frac{2\, w\, a\, (\cosh \alpha_1 - \cos \beta)}{\sinh \alpha_1} \left\{ \frac{1 - \cosh \alpha_1 \cos \beta}{(\cosh \alpha_1 - \cos \beta)^2} - \coth \alpha_1 \right.$$

$$\left. - \frac{(7 - 8\, \nu)}{4\, (1 - \nu)} \frac{\cos \beta}{\sinh \alpha_1} + 2\, e^{-\alpha_1} \cos \beta - \sum_{n=2}^{\infty} R_n \cos n\, \beta \right\} \ldots\ldots (45)$$



(a) $\alpha_1 = 0.4$ (b) $\alpha_1 = 2.0$

FIG. 4.—DIAGRAM OF STRESSES $\frac{[\sigma_\beta]_{\alpha=\alpha_1}}{w D}$ AROUND THE TUNNEL

Values of R_n are given in Table 1. Values of $[\sigma_\beta]_{\alpha=\alpha_1}$ around the hole have been calculated for a wide range of values of α_1 and for three values (0, $\frac{1}{4}$, and $\frac{1}{2}$) of ν (see Table 2). In the typical curves in Fig. 4 the dimensionless ratio $\frac{[\sigma_\beta]_{\alpha=\alpha_1}}{w D}$ (in which D is the diameter of the hole) is plotted radially from the periphery of the hole. Fig. 4(*a*) gives the variation of $[\sigma_\beta]_{\alpha=\alpha_1}$ around the hole for a small value (0.4) of α_1—that is, when the hole is close to the surface; and Fig. 4(*b*) is for a larger value (2.0) of α_1. Both are for $\nu = \frac{1}{2}$.

Table 3 gives some idea of the relation between the radius (R_2) of the hole and the distance (c) of the center of the hole from the free surface for the range of α_1 for which calculations were made.

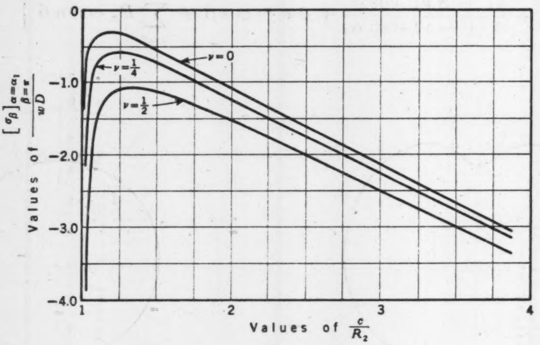

FIG. 5.—VARIATION OF THE QUANTITY $\frac{[\sigma_\beta]_{\alpha=\alpha_1, \beta=\pi}}{w D}$ AT THE HIGHEST POINT OF THE TUNNEL WALL *vs.* THE RATIO $\frac{c}{R_2}$ FOR CASE I

In Fig. 5 the quantity $\frac{[\sigma_\beta]_{\alpha=\alpha_1}}{w D}$ at the point of the hole nearest to the upper free surface is plotted against the ratio $\frac{c}{R_2}$ for three values of Poisson's ratio.

Figs. 4 and 5 and Table 2 illustrate the following significant facts for Case I:

(1) The disturbing influence of the upper free boundary is not felt until $\frac{c}{R_2}$ is less than about 1.5;

(2) For $\frac{c}{R_2} > 1.5$, the stresses increase almost linearly with the depth;

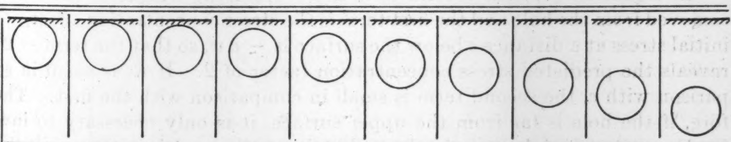
TABLE 3.—POSITION OF HOLE WITH RESPECT TO HORIZONTAL SURFACE FOR VALUES OF α_1 AND $\frac{c}{R_2}$



α_1	0.2	0.4	0.6	0.8	1.0	1.2	1.4	1.6	1.8	2.0
$\frac{c}{R_2}$	1.02	1.08	1.19	1.34	1.54	1.81	2.15	2.58	3.10	3.76

(3) For $\frac{c}{R_2} < 1.2$, the stresses increase with great rapidity as the hole approaches the upper surface of the solid;

(4) For materials of reasonable strength and density, the stresses are important only when the hole is very close to the upper surface of the solid or when it is very far from the surface;

(5) Variation of Poisson's ratio, ν, has little effect on the stresses except when the hole is very close to the upper surface; and,

(6) The stresses on the boundary of the tunnel are greatest at the lowest point of the tunnel cross-section except when α_1 is very small, in which case there are two equal maxima straddling the highest point.

In an analysis of this type, involving so much mathematical detail, it is important to determine whether or not the solution approaches, in a limiting case, a result that can be obtained directly by a simple process. When the hole is far from the upper surface, there are two factors that should be revealed in the solution: First, the stresses induced by the weight of the material removed from the hole should be very small in comparison with the stress concentration due to the initial stress in the surrounding material; and, second, by St. Venant's principle, the latter effect should be the same as for a hole in a uniform-stress field composed of the principal stresses present before the introduction of the hole. In Case I, the initial stress system is an isotropic pressure, and it is known[5] that in such a system the introduction of a hole doubles the stress.

To perform the limiting process in Equation (41), let $\alpha \rightarrow \infty$ while $a \rightarrow c$; $a \operatorname{csch} \alpha_1 \rightarrow R_2$; and $\beta \rightarrow \psi$ in which $\psi \left(= \frac{3\pi}{2} - \phi \right)$ is the angle between the radius from the center of the hole and the normal to the straight boundary, so that

$$\cos \psi = \frac{\cosh \alpha_1 \cos \beta - 1}{\cosh \alpha_1 - \cos \beta} \dots\dots\dots\dots\dots\dots (46a)$$

and

$$\sin \psi = \frac{\sinh \alpha_1 \sin \beta}{\cosh \alpha_1 - \cos \beta} \dots\dots\dots\dots\dots\dots (46b)$$

Making these substitutions in Equation (41):

$$[\sigma_\beta]_{\alpha=\alpha_1} = -2\,c\,w - R_2\,w\,\frac{3 - 4\,\nu}{2\,(1 - \nu)} \cos \psi \dots\dots\dots\dots (47)$$

In Equation (47) the second term arises from the weight of the material removed from the hole and the first term is the stress concentration effect. The initial stress at a distance c below the surface is $-\,c\,w$, so that the term $-\,2\,c\,w$ reveals the predicted stress concentration factor of 2. If R_2 is small in comparison with c, the second term is small in comparison with the first. Therefore, if the hole is far from the upper surface, it is only necessary to invoke St. Venant's principle to arrive immediately at the resulting stresses.

Cases II and III

The same general stress function, Equation (37), which was used for Case I is applicable to Cases II and III. The latter two differ from the former only in the first term of Equation (37). In Case I the first term was obtained from Equation (5*b*). In Case II, the first term is obtained from Equation (6*b*); and for Case III, Equation (7*b*) is used. Thus Cases II and III differ from Case I only by a term

$$\chi_{2,3} = G\,w\,y^3 \qquad (48)$$

in which, for Case II,

$$G = \frac{1 - 2\,\nu}{6\,(1 - \nu)} \qquad (49a)$$

and, for Case III,

$$G = \tfrac{1}{6} \qquad (49b)$$

To arrive at Cases II and III, therefore, it is only necessary to superpose on Case I the stress system arising from the initial stress represented by Equation (48). This stress system is obtained by combining the second auxiliary stress function (Equation (36)) with Equation (48) in such a manner that the stresses on the circle $\alpha = \alpha_1$ are annulled. Equation (48) can only be used with Equation (36) if it is expressed in the form $J\,f(\alpha)\cos n\,\beta$. To this end write

$$\begin{aligned}\chi_{2,3} = G\,w\,y^3 &= \frac{G\,w\,a^3\sinh^3\alpha}{(\cosh\alpha - \cos\beta)^3}\\ &= G\,w\,a^2\,J\left\{\cosh\alpha + 2\sum_{n=1}^{\infty}(\cosh\alpha + n\sinh\alpha)\,e^{-n\alpha}\cos n\,\beta\right\} \qquad (50)\end{aligned}$$

The complete stress function to be added to Case I to transform it to Cases II and III is, therefore,

$$\begin{aligned}\frac{\chi}{J} = G\,w\,a^2\Bigg\{&\cosh\alpha + 2\sum_{n=1}^{\infty}(\cosh\alpha + n\sinh\alpha)\,e^{-n\alpha}\cos n\,\beta\\ &+ B_0\,[\alpha\,(\cosh\alpha - \cos\beta) + \sinh\alpha\,(\cosh\alpha\cos\beta - 1)]\\ &+ A_1\,(\cosh 2\,\alpha - 1)\cos\beta + \sum_{n=2}^{\infty}\Big(A_n\,[\cosh\,(n+1)\,\alpha - \cosh\,(n-1)\,\alpha]\\ &+ E_n\,[(n-1)\sinh\,(n+1)\,\alpha - (n+1)\sinh\,(n-1)\,\alpha]\Big)\cos n\,\beta\Bigg\} \qquad (51)\end{aligned}$$

To determine the values of the constants, Equation (51) is substituted in Equations (20) and (22) with $w = 0$ in the latter; thus:

$$B_0 = 3\coth\alpha_1\,\mathrm{csch}^2\,\alpha_1 \qquad (52a)$$

$$A_1 = -\tfrac{3}{2}\,\mathrm{csch}^2\,\alpha_1 \qquad (52b)$$

$$A_n = -\frac{n\,(n^2 - 1)\sinh^2\alpha_1}{\sinh^2 n\,\alpha_1 - n^2\sinh^2\alpha_1} \qquad (52c)$$

and

$$E_n = \frac{n\sinh\alpha_1\,(n\sinh\alpha_1 + \cosh\alpha_1) + e^{-n\alpha_1}\sinh n\,\alpha_1}{\sinh^2 n\,\alpha_1 - n^2\sinh^2\alpha_1} \qquad (52d)$$

Again, the stresses $[\sigma_\beta]_{\alpha=\alpha_1}$ on the boundary of the hole are found by substituting Equations (52) and (51) in Equation (19*b*). The result is

$$\begin{aligned}[\sigma_\beta]_{\alpha=\alpha_1} = w\,G\,a\,(\cosh\alpha_1 - \cos\beta)\,\{&6\coth\alpha_1\,\mathrm{csch}\,\alpha_1\\ &+ 6\,\mathrm{csch}^2\,\alpha_1\cos\beta + 4\sinh\alpha_1\sum_{n=2}^{\infty}S_n\cos n\,\beta\} \qquad (53)\end{aligned}$$

in which

$$S_n = \frac{n\,(n^2 - 1)\sinh n\,\alpha_1}{\sinh^2 n\,\alpha_1 - n^2 \sinh^2 \alpha_1} \qquad (54)$$

The series in Equation (53) converges too slowly for calculation purposes. The slowly converging part may be separated out by letting

$$S_n = 2\,n\,(n^2 - 1)\,e^{-n\alpha_1} + T_n \qquad (55)$$

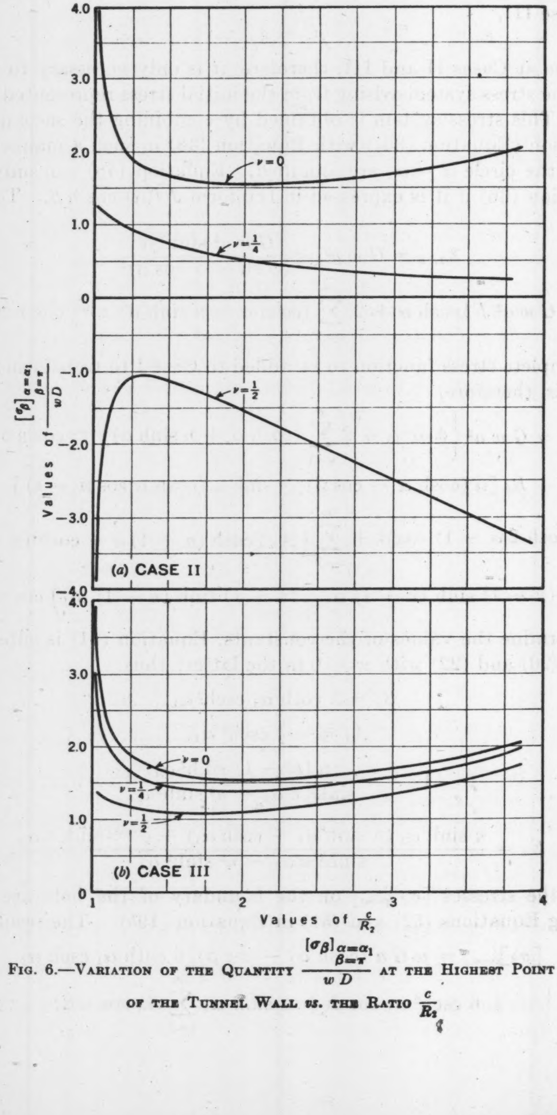


FIG. 6.—VARIATION OF THE QUANTITY $\frac{[\sigma\beta]_{\alpha=\alpha_1,\ \beta=\pi}}{w\,D}$ AT THE HIGHEST POINT OF THE TUNNEL WALL *vs.* THE RATIO $\frac{c}{R_2}$

Then, noting that

$$8\,(\cosh\alpha_1 - \cos\beta)\sum_{n=1}^{\infty} n\,(n^2 - 1)\,e^{-n\alpha_1}\cos n\,\beta = 6\,\mathrm{csch}^2\,\alpha_1$$
$$\times\,(2\cosh\alpha_1\cos 2\,\psi + \cos\psi + \cos 3\,\psi)\ldots\ldots\ldots\ldots(56)$$

and substituting Equation (55) in Equation (53):

$$[\sigma_\beta]_{\alpha=\alpha_1} = w\,G\,a\,(\cosh\alpha_1 - \cos\beta)\{6\coth\alpha_1\,\mathrm{csch}\,\alpha_1 + 6\,\mathrm{csch}^2\,\alpha_1\cos\beta$$
$$+\,4\sinh\alpha_1\sum_{n=2}^{\infty} T_n\cos n\,\beta\} + 6\,w\,G\,a\,\mathrm{csch}\,\alpha_1$$
$$\times(\cos\psi + 2\cosh\alpha_1\cos 2\,\psi + \cos 3\,\psi)\ldots\ldots\ldots\ldots(57)$$

Values of T_n are given in Table 4. Values of $[\sigma_\beta]_{\alpha=\alpha_1}$ for Case II and Case III are obtained by adding Equations (45) and (57) with G given by Equations (49*a*) and (49*b*), respectively. The results are given in Table 5.

The curves in Fig. 6 show the variation of the stress in terms of $\frac{[\sigma_\beta]_{\alpha=\alpha_1}}{w\,D}$, at the highest point of the tunnel as $\frac{c}{R_2}$ is varied. The conclusions that were drawn for Case I also hold for Cases II and III with the following additional comments:

(1) The wide variation of the stresses for the three separate cases shows the necessity of knowing the initial state of stress in the solid; and,

(2) The apparent great change in the stresses of Case II with variation of Poisson's ratio is to be attributed to variation of the state of initial stress rather than to any marked change with Poisson's ratio.

Once again it is desirable to check the results by applying a limiting process as in the preceding section. In this case there is available, for comparison, Yamaguti's approximate solution[3] for a hole far from the upper free surface with initial stresses corresponding to Case II.

2.0	2.52	0.61	−3.08	−5.54	−5.61	−4.04	−1.94	−0.05	1.21	1.65

Note: Case II, $\nu = \frac{1}{2}$ and Case I, $\nu = \frac{1}{2}$ are identical.

Applying the limiting conditions:

$$[\sigma_\beta]_{\alpha=\alpha_1} = \frac{w}{1-\nu}\left\{-c - \tfrac{1}{2}R_2\cos\psi + 2(1-2\nu)\,c\cos 2\psi + (1-2\nu)\,R_2\cos 3\psi\right\} \quad \text{(58)}$$

In order to compare $[\sigma_\beta]_{\alpha=\alpha_1}$ in Equation (58) with Yamaguti's σ_θ (written $\overline{\theta\theta_1}$) note that his symbol θ is given by $\theta = \pi - \psi$.

When this substitution is made, the two formulas check except for an error in sign[17b] in Yamaguti's work.

APPENDIX I

Dead Load Moment and Thrust in an Arch

The results of the preceding sections can be applied to the arch-like structure formed between $\alpha = 0$ and $\alpha = \alpha_1$ for small values of α_1; but, when α_1 is small, the infinite series in the stress formulas converge very slowly. This is due to the fact that, for $\alpha_1 = 0$, the series actually diverge. Consequently, the computations are exceedingly laborious. The difficulty may be avoided if it is observed that the resultant force and couple on a section $\beta =$ *constant* connecting the two boundaries may be expressed in finite terms. In what follows, this statement will be proved and the results applied to Case I as an illustrative example.

Let s_α be an arc of the curve $\beta =$ *constant*, measured positively in the direction of increasing α. In traveling along the curve in the positive direction, the right-hand side is called the outside and the left-hand side the inside. Let $\bar{X}$ and $\bar{Y}$ be the forces per unit of thickness parallel to the x-axis and the y-axis which the material outside of s_α exerts on the material inside of s_α per unit of length of s_α. Then, if l and m are the direction cosines of the outward drawn normal to s_α referred to the x-axis and the y-axis:[18]

$$\bar{X} = l\,\sigma_x + m\,\tau_{xy} \qquad (59a)$$

and

$$\bar{Y} = l\,\tau_{xy} + m\,\sigma_y \qquad (59b)$$

Now $l = \dfrac{dy}{ds_\alpha}$; $m = -\dfrac{dx}{ds_\alpha}$ and σ_x, σ_y and τ_{xy} are given, in terms of χ and Ω, by Equations (1). Hence

$$\bar{X} = \frac{dy}{ds_\alpha}\left(\frac{\partial^2\chi}{\partial y^2} + \Omega\right) + \frac{dx}{ds_\alpha}\frac{\partial^2\chi}{\partial x\,\partial y} = \frac{d}{ds_\alpha}\left(\frac{\partial\chi}{\partial y}\right) + \Omega\frac{dy}{ds_\alpha} \qquad (60a)$$

and

$$\bar{Y} = -\frac{dy}{ds_\alpha}\frac{\partial^2\chi}{\partial x\,\partial y} - \frac{dx}{ds_\alpha}\left(\frac{\partial^2\chi}{\partial x^2} + \Omega\right) = -\frac{d}{ds_\alpha}\left(\frac{\partial\chi}{\partial x}\right) - \Omega\frac{dx}{ds_\alpha} \qquad (60b).$$

The x and y components of resultant force on the entire arc between the straight and circular boundaries are found by integrating Equations (60) along s_α, from the point of intersection of s_α with $\alpha = 0$ to the point of intersection of s_α with $\alpha = \alpha_1$. Calling these total x and y components H and V, respectively:

$$H = \int_0^{\alpha_1} \bar{X}\,ds_\alpha = \left[\frac{\partial\chi}{\partial y}\right]_0^{\alpha_1} + \int_0^{\alpha_1} \Omega\,dy \qquad (61a)$$

and,

$$V = \int_0^{\alpha_1} \bar{Y}\,ds_\alpha = -\left[\frac{\partial\chi}{\partial x}\right]_0^{\alpha_1} - \int_0^{\alpha_1} \Omega\,dx \qquad (61b)$$

[17b] The error in Yamaguti's paper first appears in his Equations (16). The second term in the second of his Equations (16) should be preceded by a plus sign instead of a minus sign. The error is carried through the remainder of the paper so that his formula for $\overline{\theta\theta}_1$ is incorrect.

[18] "A Treatise on Photo-Elasticity," by E. G. Coker and L. N. G. Filon, Cambridge University Press, 1931, p. 507.

Now $\dfrac{\partial \chi}{\partial y} = \dfrac{\partial \alpha}{\partial y}\dfrac{\partial \chi}{\partial \alpha} + \dfrac{\partial \beta}{\partial y}\dfrac{\partial \chi}{\partial \beta}$; or,

$$\frac{\partial \chi}{\partial y} = \frac{\partial \alpha}{\partial y}\left(J\frac{\partial}{\partial \alpha} + \frac{\partial J}{\partial \alpha}\right)\left(\frac{\chi}{J}\right) + \frac{\partial \beta}{\partial y}\left(J\frac{\partial}{\partial \beta} + \frac{\partial J}{\partial \beta}\right)\left(\frac{\chi}{J}\right) \ldots\ldots (62a)$$

and, $\dfrac{\partial \chi}{\partial x} = \dfrac{\partial \alpha}{\partial x}\dfrac{\partial \chi}{\partial \alpha} + \dfrac{\partial \beta}{\partial x}\dfrac{\partial \chi}{\partial \beta}$; or,

$$\frac{\partial \chi}{\partial y} = \frac{\partial \alpha}{\partial x}\left(J\frac{\partial}{\partial \alpha} + \frac{\partial J}{\partial \alpha}\right)\left(\frac{\chi}{J}\right) + \frac{\partial \beta}{\partial x}\left(J\frac{\partial}{\partial \beta} + \frac{\partial J}{\partial \beta}\right)\left(\frac{\chi}{J}\right) \ldots\ldots (62b)$$

Therefore

$$H = \left[\frac{\partial \alpha}{\partial y}\left(J\frac{\partial}{\partial \alpha} + \frac{\partial J}{\partial \alpha}\right)\left(\frac{\chi}{J}\right) + \frac{\partial \beta}{\partial y}\left(J\frac{\partial}{\partial \beta} + \frac{\partial J}{\partial \beta}\right)\left(\frac{\chi}{J}\right) + \int \Omega\, dy\right]_0^{\alpha_1} \ldots (63a)$$

and,

$$V = -\left[\frac{\partial \alpha}{\partial x}\left(J\frac{\partial}{\partial \alpha} + \frac{\partial J}{\partial \alpha}\right)\left(\frac{\chi}{J}\right) + \frac{\partial \beta}{\partial x}\left(J\frac{\partial}{\partial \beta} + \frac{\partial J}{\partial \beta}\right)\left(\frac{\chi}{J}\right) + \int \Omega\, dx\right]_0^{\alpha_1} \ldots (63b)$$

To find the total moment on the section, take moments of $\tau_{\alpha\beta}$ on β = *constant* about the center of the circle β = *constant* as the moment center. Then

$$M = \rho_1 \int_0^{\alpha_1} \tau_{\alpha\beta}\, ds_\alpha = \frac{J^2}{\left(\dfrac{\partial J}{\partial \beta}\right)_{\alpha 1}} \left[\frac{\partial}{\partial \beta}\left(\frac{\chi}{J}\right)\right]_0^{\alpha_1} \ldots\ldots\ldots\ldots (64)$$

In Equations (63) and (64) $\dfrac{\chi}{J}$ occurs only in the form of its boundary values and the boundary values of its first derivatives with respect to α and β; but, by Equations (20) and (22), these quantities are given in finite terms. Hence, by using Equations (20) and (22) in Equations (63) and (64), formulas for the force and couple on a section β = *constant*, connecting the two boundaries, may be found readily in finite terms.

Applying Equations (63) and (64) to Case I:

$$H = \frac{w\, a^2}{2}\left(\frac{1 - 2\,\nu}{2(1 - \nu)}\,\alpha_1 \operatorname{csch}^2 \alpha_1 - \coth \alpha_1\right) \ldots\ldots\ldots (65a)$$

$$V = -\frac{w\, a^2}{2}\left\{\left(\phi_1 - \frac{\pi}{2}\right)(\csc^2 \beta - \operatorname{csch}^2 \alpha_1) + \frac{2 \coth \alpha_1 \sin \beta}{\cosh \alpha_1 - \cos \beta}\right.$$
$$\left. - \frac{(1 - \cosh \alpha_1 \cos \beta)(\cosh \alpha_1 + \cos \beta)}{\sin \beta \sinh \alpha_1 (\cosh \alpha_1 - \cos \beta)}\right\} \ldots\ldots\ldots\ldots (65b)$$

and,

$$M = \frac{w\, a^3}{2} \operatorname{csch}^2 \alpha_1 \left\{\left(\phi_1 - \frac{\pi}{2}\right)\cot \beta - \frac{\sinh \alpha_1}{\cosh \alpha_1 - \cos \beta}\right.$$
$$\left. + \frac{5 - 6\,\nu}{2(1 - \nu)}(\alpha_1 \coth \alpha_1 - 1) + \sinh \alpha_1\, e^{-\alpha_1}\right\} \ldots\ldots\ldots (65c)$$

In terms of the dimensions shown in Fig. 7 these become

$$H = \frac{w}{2}\left\{\frac{1 - 2\,\nu}{2\,(1 - \nu)} R_2^2 \log \frac{c + a}{R_2} - a\, c\right\} \ldots\ldots\ldots\ldots (66a)$$

$$V = -\frac{w}{2}\{\Theta\,(R_1^2 - R_2^2) + y_1 f + x_1 c\} \ldots\ldots\ldots\ldots (66b)$$

and,

$$M = \frac{w}{2} R_2^2 \left\{ \Theta f - y_1 + \frac{5 - 6\nu}{2} \left(c \log \frac{c + a}{R_2} - a \right) + a^2 \frac{(c - a)}{R_2^2} \right\} \ldots (66c)$$

To determine the moment (M_0) at the crown of the arch it should be observed that

$$\lim_{\beta \to \pi} \Theta \cot \beta = - \frac{\sinh \alpha_1}{\cosh \alpha_1 + 1} = - \frac{y_0}{a} \ldots\ldots\ldots\ldots\ldots (67)$$

Hence

$$M_0 = \frac{w}{2} R_2^2 \left\{ - 2 y_0 + \frac{5 - 6\nu}{2} \left(c \log \frac{c + a}{R_2} - a \right) + \frac{a^2 (c - a)}{R_2^2} \right\} \ldots (68)$$

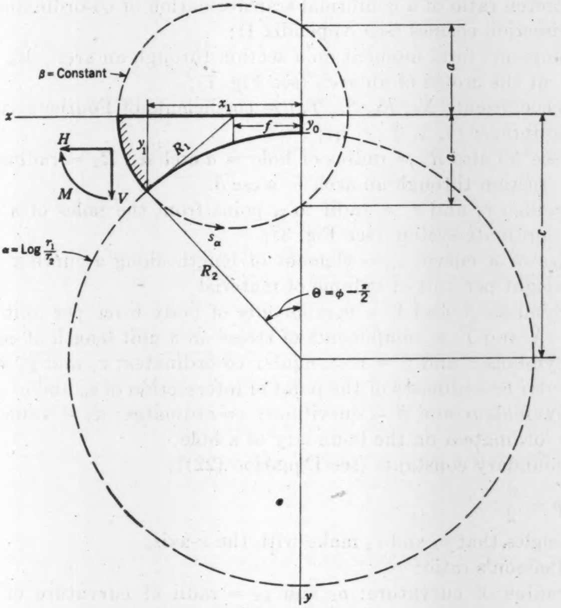

FIG. 7.—DIMENSIONS OF ARCH

APPENDIX II

NOTATION

The following notation conforms essentially with American Standard Symbols for Mechanics, Structural Engineering, and Testing Materials[19] compiled by a committee of the American Standards Association with Society representation, and approved by the Association in 1932. Where additional symbols are required, the notation used by Professor Timoshenko[20] is followed.

---

[19] ASA—Z10A—1932.

[20] "Theory of Elasticity," by S. Timoshenko, New York, 1934.

A = a constant ($A_0 \cdots A_n$; $B_0 \cdots B_n$; $C_0 \cdots C_n$; $D_0 \cdots D_n$);

a = a distance from the origin to a pole, in bipolar co-ordinates;

c = distance of the center of hole from the origin = $a \coth \alpha_1$

D = diameter of hole; (see also A)

d = depth below ground surface, to a horizontal plane (see Fig. 2);

e = Naperian base = $2.718 \cdots$;

f = $a \cot \beta$ (see Fig. 7);

G = a constant defined in Equation (49);

H, V (see Fig. 7); H and V = horizontal and vertical components of a resultant force, on a section through the arch;

$i = \sqrt{-1}$;

J = stretch ratio of a conformal transformation of co-ordinates;

l, m = direction cosines (see Appendix I);

M = moment; total moment on a section through an arch; M_0 = moment at the crown of an arch (see Fig. 7);

N = a coefficient (N_n, R_n, S_n, T_n) = coefficients of Fourier series;

n = an integer ($1, 2, 3 \cdots n$);

R (see N) also R_2 = radius of hole = $a \operatorname{csch} \alpha_1$; R_1 = radius of circular section through an arch = $a \csc \beta$.

r = radius; r_1 and r_2 = radii to a point from the poles of a bipolar coordinate system (see Fig. 3);

s = arc of a curve; s_α = element of length along a curve β = *constant;*

w = weight per unit of volume of material;

X, Y Symbols X and Y = components of body force per unit of volume; $\bar{X}$ and $\bar{Y}$ = components of stress on a unit length of curve;

x, y Symbols x and y = rectangular co-ordinates; x_1 and y_1 = rectangular co-ordinates of the point of intersection of s_α and α_1 (see Fig. 7);

α Symbols α and β = curvilinear co-ordinates; α_1 = value of the coordinate α on the boundary of a hole;

ζ, η, ξ = boundary constants (see Equation (22));

$\Theta = \phi - \frac{\pi}{2}$;

θ_1, θ_2 = angles that r_1 and r_2 make with the x-axis;

ν = Poisson's ratio;

ρ = radius of curvature; ρ_1 and ρ_2 = radii of curvature of the curves β = *constant* and α = *constant*, respectively;

σ = unit normal stress; σ_x, σ_y = components of unit normal stress in rectangular co-ordinates; σ_α, σ_β = components of unit normal stress in curvilinear co-ordinates;

τ = unit shear stress; τ_{xy} = unit shear stress in rectangular co-ordinates; $\tau_{\alpha\beta}$ = unit shear stress in curvilinear co-ordinates;

ϕ = angle between the x-axis and the tangent to the curve β = *constant;*

χ = stress function;

$\psi = \frac{3\pi}{2} - \phi$;

Ω = body-force function; and,

∇^2 = Laplace's two-dimensional operator ($\nabla^4 = \nabla^2\nabla^2$).

DISCUSSION

W. O. Richmond,[21] Esq. (by letter).—The stress distribution due to gravity in a semi-infinite elastic body pierced by a circular hole is an interesting problem and the author's treatment of it is a complete one. The application of the results in practise depend, of course, upon the accuracy with which the assumptions are fulfilled. If the shape of the tunnel is other than circular (as it often is), a mathematical solution is practically impossible and recourse must be had to experimental methods.

An interesting experimental approach to this problem was developed by Mr. S. Yamaguti,[22] whose method consisted of casting a flat plate of agar-agar in a horizontal position. A network of lines was placed on the plate, and a hole was cut, of a shape appropriately representing the tunnel profile. When the model was placed in a vertical position, the strain in the material due to its own weight could be measured from the distortion of the originally parallel lines, and hence the stresses could be determined. For a round tunnel profile Mr. Yamaguti obtained good agreement between his mathematical solution and the results of his model test.

Mr. Yamaguti's method of test reproduces the author's Case II with the appropriate value of Poisson's ratio for agar-agar. The author's Case I could also be reproduced by this method. It would only be necessary to cast the agar-agar plate in a vertical position, so that the stress distribution in the unpierced plate would approximate a hydrostatic pressure.

A second experimental approach to the problem is by the method of photo-elasticity. If the tunnel profile is some distance below the surface, the stress distribution may be obtained approximately by the method of superposition, as stated by the author. Assuming that the original stress distribution is as represented by Case II, for instance, the boundary stress around the profile is just determined for a uniform compression in a vertical direction of magnitude.

$$\sigma_y = - w\,c \qquad \text{(69)}$$

Then the boundary stress is determined, for a stress at right angles, of magnitude

$$\sigma_x = - \frac{\nu}{1-2\,\nu}\,w\,c \qquad \text{(70)}$$

in which the symbols used are those of the author in Fig. 2, and c is the distance of the hole from the free surface. The stress on the boundary is then obtained by adding the two boundary stress distributions. For a non-circular profile the boundary stresses are most easily determined by photo-elastic tests.

This procedure is sufficiently accurate if the profile is some distance below the surface. For the case shown in Fig. 4(*b*) (that is, for a value of Poisson's ratio of ½ and $\alpha_1 = 2.0$), this approximate method gives a uniform compressive stress around the boundary of the tunnel of $- 3.76\, w\, D$, in which w = density of the material, and D = diameter of the circular profile. The maximum stress by the author's computation is $-4.26\, w\, D$. The error in the approximate method is thus slightly more than 10%, which is perhaps accurate enough for practical purposes. Thus, the conclusion may be drawn that if the tunnel is more than four radii, or two diameters from the surface, the approximate solution obtained by superposition is sufficiently accurate.

[22] "On the Investigation of the Stress Distribution in a Tunnel with Agar-agar Model Experiments," by S. Yamaguti, *Proceedings*, Third International Cong. for Applied Mechanics, Vol. II, 1930, pp. 150–154.

A few years ago the writer (working under the direction of A. Nadai at the Westinghouse Research Laboratories) made some photo-elastic tests on holes of tunnel profile at the suggestion of F. C. Carstarphen, M. Am. Soc. C. E. The profiles tested were squares with various fillet radii at the corners; the ratio of fillet radius, r, to side of square, D, had the values $\frac{r}{D} = \frac{1}{3}, \frac{1}{6}$, and $\frac{1}{12}$. The boundary stress distribution was obtained photo-elastically when the bakelite plate which contained the holes was subjected to a pure tension parallel to an axis of symmetry perpendicular to the sides of the holes. The stress concentration factors (that is, the ratio of the maximum stress on the boundary of the hole to the stress in the plate a long way from the hole) from these tests are shown in Table 6. For the sake of completeness, the case of the circular hole in a tensile stress field, for which $\frac{r}{D} = \frac{1}{2}$, is included, the results for which can be obtained by computation.[23] It is interesting to note that a minimum stress concentration factor seems to result for a value of $\frac{r}{D}$ of about $\frac{1}{6}$. The stress concentration factor for a square hole with sharp corners would be theoretically infinite.

TABLE 6.—STRESS CONCENTRATION FACTORS

Item No.	Description	RATIO OF FILLET RADIUS, r, TO THE SIDE OF THE SQUARE, D			
		$\frac{1}{2}$	$\frac{1}{3}$	$\frac{1}{6}$	$\frac{1}{12}$
1	Stress concentration factor for tension or compression........	3	2.6	2.5	2.6
2	Maximum compressive stress on boundary of tunnel profile (Case II, $\nu = \frac{1}{4}$)..	2.7	2.4	2.4	2.5

The stress distribution around the boundary of tunnels of similar cross-section was then computed from the boundary stresses determined by the photo-elastic tests. The case solved by the writer was the author's Case II, in which the principal stresses before the tunnel existed were given by Equations (69) and (70). The results obtained by this procedure for a value of Poisson's ratio of $\frac{1}{4}$ are shown in Item 2, Table 6. These results should be sufficiently accurate, provided that the tunnel is at least two diameters below the surface, that the material in which the tunnel is driven behaves elastically, and that the original principal stresses are as assumed.

---

[23] "Theory of Elasticity," by S. Timoshenko, 1934, p. 75.

Jacob Feld,[24] M. Am. Soc. C. E. (by letter).—For the condition explained in this paper—namely, a circular tunnel in a uniform elastic material—Mr. Mindlin's solution is the most complete available. For use in practical cases, however, the following items must be taken into account:

I.—The internal stress in the rock in its natural condition, which stress may be relieved in the local vicinity of the tunnel by the removal of the tunnel rock.

II.—The percentage of error resulting from the use of the method and formulas in this paper when rock conditions cannot be assumed as isotropic. It is seldom that a tunnel is driven through a uniform granite, which is probably the nearest approach to the material assumed in this paper. The more usual cases are tunnels driven through laminar rock, such as shales, schists, or limestones. It is extremely doubtful whether the stress determinations resulting from the formulas in this paper can be applied to a case where a blocky limestone is encountered, or, to take a different example, where schist in thin layers, lying edgewise to the face of the tunnel, is encountered.

III.—The effect on stresses around the tunnel if temporary bracing is wedged against the exposed rock during driving, or the effect on the rock stresses as the tunnel is lined with concrete and grouted under pressure; also the effect of various grouting pressures in balancing or over-balancing rock stresses.

In taking the foregoing suggestions into consideration, it might be pertinent to consider the assumption made under the heading "Statement of the Problem" that, at the circular boundary, the normal stress and the shearing stress are equal to zero. Such an assumption is not correct when rock is encountered which requires bracing to prevent movement. It seems to the writer that in the three cases mentioned as covering the initial states of the rock, although they cover a great range of possibilities, such range is chiefly in the variation of the Poisson ratio in Case II. Case I is that of hydrostatic pressure which may be applicable at tremendous distances below the earth's surface in rocks that are under such pressure that they are practically liquid, and Case III would only apply where a tunnel is driven through blocks of rock with open vertical seams, which case could not be considered isotropic. With reference to Case II and its dependence upon the Poisson ratio of the material, it might well be emphasized that such ratio may vary for rocks, depending upon the amount of the stress. However, as stated in Mr. Mindlin's paper, such variation has little effect on the stresses themselves, except when the tunnel is unusually close to the open surface. It is for such a condition (namely, shallow tunnels) that a careful stress analysis is most necessary.

J. H. A. Brahtz,[25] Esq. (by letter).—Congratulations are due the author for his excellent presentation of a very difficult theoretical subject. It is highly gratifying to have studies of this caliber brought to the attention of the engineering profession. In the mathematical theory of elasticity, relatively few exact solutions exist that may be applied directly to engineering problems. This paper is a definite contribution to this small group of exact solutions.

---

[24] Cons. Engr., New York, N. Y.

[25] Director, Photoelastic Laboratory, U. S. Dept. of the Interior, Bureau of Reclamation, Denver, Colo.

A characteristic behavior of additions to the exact-solution group seems to be that the underlying mathematics become more abstruse and complicated with each addition. This is particularly true in the cases treated by Mr. Mindlin, but in no way detracts from the value of the paper. However, it does limit its broad use and application to a relatively small group of engineers with a highly specialized mathematical background. Apparently, the author is well aware of this limitation and has minimized the attendant difficulties by presenting, in tabular and graphical form, the results of many computations. These simplify and reduce the labor greatly in applying the theoretical results to engineering problems.

In his study of the stresses due to body forces, Mr. Mindlin has considered three possible conditions that differ only in the ratio of horizontal stress to vertical stress along the vertical boundaries. To the mathematician the choice of this ratio represents no problem; it is merely called a boundary condition and is assumed to be known. To the practicing engineer the proper choice of this ratio is of utmost importance. For lack of definite information on the proper value of this ratio, the engineer is likely to employ a value that produces the most critical state of stress. This is on the side of safety but scarcely ever on the side of economy. Although the author has left this value "floating" (as he should, since a knowledge of it comes under the science of soil mechanics or geophysics, and not mathematics), it seems important to stress the need of experimental and statistical knowledge on this phase of foundation engineering.

It would have been interesting if the author had included one or more photoelastic checks and had compared the experimental maximum shear stresses with the computed values. It is realized, however, that body forces are difficult to apply to photoelastic models and that even when M. A. Biot's[26] method of employing boundary forces is used, formal and practical difficulties arise in the application of a continuously varying normal load on the closed boundary that corresponds to the tunnel surface.

Mr. Mindlin confined the application of the bipolar theory to body force or "dead load" stresses. For structures having shapes similar to those given in the paper, other common conditions of loading exist. These include the cases in which either the straight or circular boundaries are subjected to uniformly distributed loads. Although the general form for these cases has been given elsewhere,[27] it is felt that the particular cases in which one boundary is a straight line should be included in the paper, for completeness. Loadings of this type frequently arise in engineering practice. Usually they occur simultaneously with the case treated by the author. An example of this condition would be a circular tunnel in bed-rock below a river-bed or earth embankment. Sometimes they occur as the only loading; for example, a vertical shaft near the up-stream face of a masonry dam or a pressure pipe, or conduit, near a free surface. The latter is the case of uniform normal pressure on the inner boundary.

The writer is presenting the results obtained by auxiliary studies covering the conditions of uniform normal loads along the boundaries. The first part of

[26] *Journal of Applied Mechanics*, June, 1935.

[27] See, for example, "A Treatise on Photo-Elasticity," by E. G. Coker and L. N. G. Filon, Cambridge, University Press, 1931, p. 313, *et seq.*

the study is purely mathematical and is based upon Jeffery's general theory for stresses in a circular plate having an eccentric hole. A uniform normal pressure is applied to the outer boundary. If the radius of this boundary is assumed to increase without limit, the segment of the outer boundary in the vicinity of the hole approaches the limiting condition of a straight line. It should be noted that, in this limiting process, the outer boundary is still loaded on all sides, and the stress formulas obtained for the limiting case must be for the condition of the infinite boundaries, as well as the straight boundary, being loaded uniformly.

Although this is an important loading condition, a more common condition is one in which the straight boundary is loaded fully, and the vertical infinite boundaries are loaded only partly. The stresses for this condition can be obtained, however, by combining the results of a mathematical solution with those of photoelastic experiments, or by combining two mathematical solutions. The two mathematical solutions to be combined are the one given by the writer in this discussion and the solution by Mr. Jeffery referred to by the author.[11] However, Mr. Mindlin has called attention to an inconsistency in Mr. Jeffery's solution, and, rather than attempt to correct this fundamental error, the writer has used a combination of experiment and theory. The experimental problem treated by the writer is the problem treated by Mr. Jeffery. A table of numerical values for stresses at critical points has been developed by S. Timoshenko.[28] For the smallest value of $\frac{d}{r}$ given in the table, the boundary stress on the straight boundary opposite the hole is approximately twice the average stress in the plate, and of opposite sign. In his experimental study the writer was unable to note any change of sign in the stress along this boundary. An inspection of the isochromatic photographs included herewith bears out this point. Finally, the stresses are given for the cases in which a uniform pressure exists only on the internal boundary.

Another interesting application of bipolar co-ordinates arises in connection with the problem of percolation into a tunnel in pervious foundation or a shaft of circular cross-section situated near the up-stream face of a masonry dam.

Uniform Normal Loads on Boundaries.—Again making use of the bipolar transformation, shown in Fig. 1, the following boundary conditions are specified:

(I) The boundary $\alpha = \alpha_1$ is subjected to a normal load $\sigma_\alpha = 1$ and is free of shear—that is, $\tau_{\alpha\beta} = 0$.

(II) The boundary $\alpha = \alpha_2$ is free of load—that is, $\sigma_\alpha = \tau_{\alpha\beta} = 0$; and α_1 and α_2 are any of the positive α-circles shown in Fig. 1.

Now consider the function (see Equation (30))—

$$\frac{x_6}{J} = F = \sum_{n=0}^{\infty} f_n(\alpha) \cos n\beta \qquad (71)$$

The first two functions ($n = 0$ and $n = 1$) are

$$F_0 = A_0 \cosh \alpha + B_0 \alpha \cosh \alpha + C_0 \sinh \alpha + D_0 \alpha \sinh \alpha \qquad (72a)$$

---

[28] "Theory of Elasticity," by S. Timoshenko, New York. 1934, p. 79.

and

$$F_1 = (A_1 \cosh 2\alpha + B_1 + C_1 \sinh 2\alpha + D_1 \alpha) \cos \beta \ldots\ldots (72b)$$

The relations, $D_0 = 0$ and $-D_1 = B_0$, have been shown by the author to exist in order that displacements may be single valued; and he has shown that A_0 may be placed equal to zero since $B_1 \cos \beta$ gives the same type of stress. Hence $F_0 = -D_1 \alpha \cosh \alpha$ and

$$F = F_0 - F_1 = (A \cosh 2\alpha + B + C \sinh 2\alpha) \cos \beta + D\alpha (\cos \beta - \cosh \alpha) \ldots\ldots (73)$$

Substitution of Equation (73) in the general stress equations (Equations (19)) gives

$$a\,\sigma_\alpha = A (\cosh 2\alpha - 2 \sinh 2\alpha \sinh \alpha \cos \beta) + B + C (\sinh 2\alpha - 2 \cosh 2\alpha \sinh \alpha \cos \beta) + D \sinh \alpha (\cosh \alpha - \cos \beta) \ldots\ldots (74a)$$

$$a\,\sigma_\beta = A [2 \cosh \alpha \cos \beta - \cosh 2\alpha (4 \cos^2 \beta - 1 - 2 \cosh \alpha \cos \beta)] + B + C [2 \sinh \alpha \cos \beta - \sinh 2\alpha (4 \cos^2 \beta - 1 - 2 \cosh \alpha \cos \beta)] - D \sinh \alpha (\cosh \alpha - \cos \beta) \ldots\ldots (74b)$$

and

$$a\,\tau_{\alpha\beta} = (2 A \sinh 2\alpha + 2 C \cosh 2\alpha + D) (\cosh \alpha - \cos \beta) \sin \beta . (74c)$$

The constants A, B, C, and D are now determined by the boundary conditions (I) and (II). Omitting mathematical details, the constants are found to be:

$$A = \frac{a}{2} \frac{\sinh (\alpha_2 + \alpha_1)}{\sinh (\alpha_2 - \alpha_1) [1 - \cosh (\alpha_2 + \alpha_1) \cosh (\alpha_2 - \alpha_1)]} \ldots (75a)$$

$$B = A \frac{\sinh (\alpha_2 - \alpha_1) - \sinh 2\alpha_2 \cosh (\alpha_2 - \alpha_1)}{\sinh (\alpha_2 + \alpha_1)} \ldots\ldots (75b)$$

$$C = -A \coth (\alpha_2 + \alpha_1) \ldots\ldots (75c)$$

and

$$D = 2A \frac{\cosh (\alpha_2 - \alpha_1)}{\sinh (\alpha_2 + \alpha_1)} \ldots\ldots (75d)$$

It has been stated that Equations (75) are applicable to any two circular boundaries, $\alpha = \alpha_1$ and $\alpha = \alpha_2$, as shown in Fig. 1. It gives the stresses for unit normal tension on the boundaries of a circular cylinder with an eccentric circular hole.[27] If the outer boundary is free of force, and if a unit compression force acts on the boundary of the hole, it is only necessary to superimpose a unit hydrostatic state of compression, $\sigma_\alpha' = \sigma_\beta' = -1$, $\tau_{\alpha\beta}' = 0$, on to the stresses of the first solution.

Application to a Circular Tunnel.—If the ground surface is assumed plane (that is, a cylinder of infinite radius), α_1 is placed equal to zero in the formulas; hence, Equations (75) become

$$A = \frac{a}{2 (1 - \cosh^2 \alpha_2)} \ldots\ldots (76a)$$

$$B = A (1 - 2 \cosh^2 \alpha_2) \ldots\ldots (76b)$$

$$C = -A \coth \alpha_2 \ldots\ldots (76c)$$

and

$$D = -2C \ldots\ldots (76d)$$

The values of the constants for this case are plotted in Fig. 8 for various ratios of $\frac{d}{r}$, in which d is the depth of the center below the ground surface and r is the radius of the tunnel. The next step is to plot the stresses for unit com-

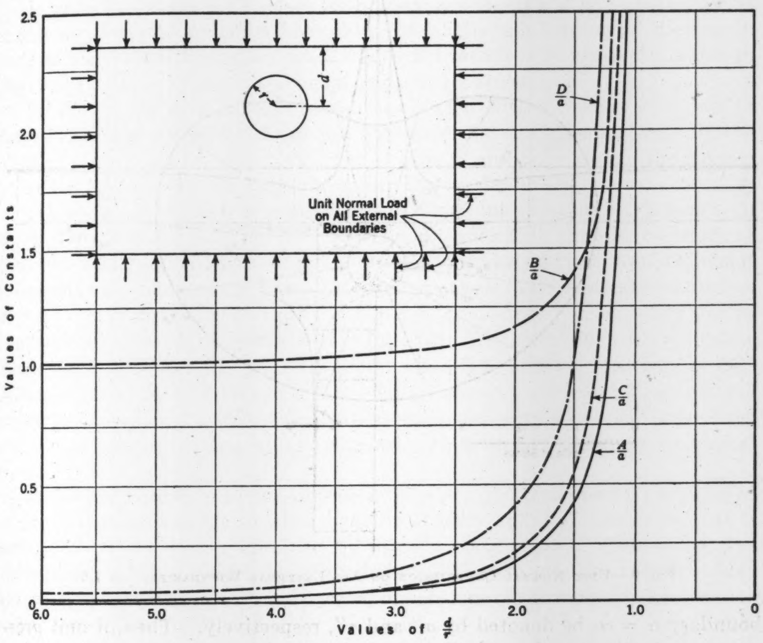

FIG. 8.—CONSTANTS A, B, C, AND D WHEN $\alpha_1 = 0$

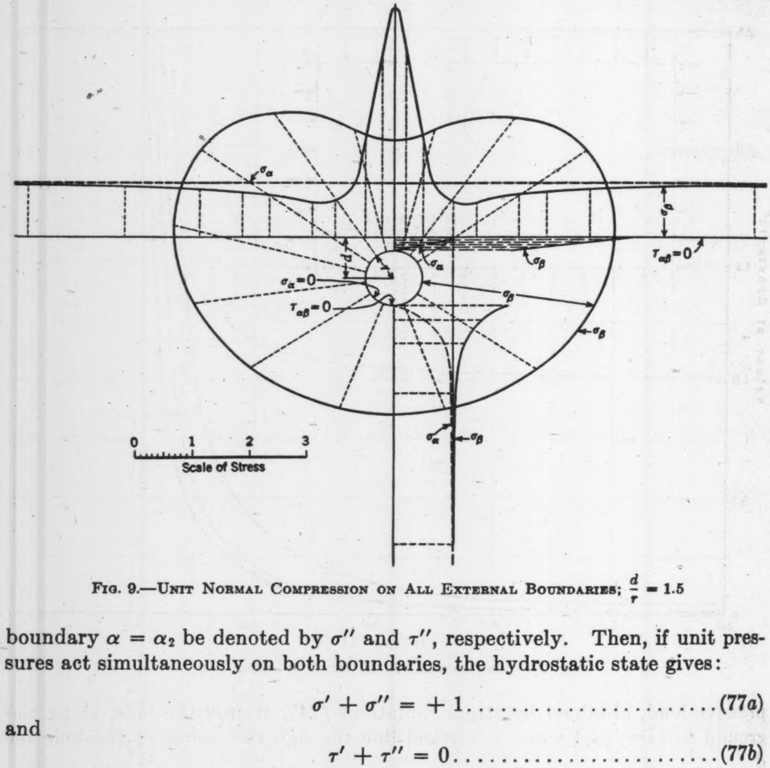
pressive load, obtained by stress Equations (74), around the hole, along the ground surface, and along a vertical line through the center of the hole for $\frac{d}{r} = 6, 5, 4, 3, 2, 1, 1.5$ and 1.25, respectively.[29] All stresses due to this loading are compression and can be plotted in terms of the unit load. Fig. 9 illustrates the form of curves for $\frac{d}{r} = 1.5$.

As stated previously, the computations made for a unit normal load acting on the outer boundary may also be used to determine the stresses in the foundation due to a unit normal load acting on the boundary of the hole. It is obvious that, if a unit normal load is applied simultaneously on both the outer and inner boundaries, all points in the body will have unit normal stress in all directions. Such a body is said to be in a hydrostatic state of stress. Principal stresses are equal to the same quantity at all points, and all shear stresses are zero.

---

[29] *Technical Memorandum No. 597*, U. S. Bureau of Reclamation.

Let a normal stress at any point due to a unit normal load acting on the boundary $\alpha = 0$ be denoted σ' and the shear by τ'. Furthermore, let a normal stress and shear at the same point due to a unit normal load acting on the boundary $\alpha = \alpha_2$ be denoted by σ'' and τ'', respectively. Then, if unit pressures act simultaneously on both boundaries, the hydrostatic state gives:



σ_α
σ_β
$\tau_{\alpha\beta}=0$
d
σ_α
σ_β
$\sigma_\alpha=0$
$\tau_{\alpha\beta}=0$
σ_β
σ_β
σ_α
σ_β
0 1 2 3
Scale of Stress

FIG. 9.—UNIT NORMAL COMPRESSION ON ALL EXTERNAL BOUNDARIES; $\frac{d}{r} = 1.5$

$$\sigma' + \sigma'' = +1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (77a)$$

and

$$\tau' + \tau'' = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (77b)$$

if compression stress is considered positive.

By solving Equations (77), the normal stress σ'' and the shears τ'' can be found in terms of σ' and τ', respectively, as follows:

$$\sigma'' = 1 - \sigma' \ldots\ldots\ldots\ldots\ldots\ldots\ldots (78a)$$

and

$$\tau'' = -\tau' \ldots\ldots\ldots\ldots\ldots\ldots\ldots (78b)$$

A negative result will then denote tension. Hence, if the normal stresses found for a unit normal load acting on $\alpha = 0$ are deducted from unity, the stresses due to a unit normal load acting on $\alpha = \alpha_2$ will be obtained. The shears found at any point of the body for a unit load acting on $\alpha = 0$ will be of equal magnitude but opposite direction for a unit load acting on $\alpha = \alpha_2$.

Equations (78) are easily solved graphically by curves such as those in Fig. 9. It will be found that the stresses σ_α'' are still compressive and attain their maximum value at the hole, diminishing asymptotically to zero away from the hole. The stresses σ_β'' become tension, maximum at the hole, and also approach zero asymptotically.

In order to obtain the stresses for a boundary loading of any magnitude, it is only necessary to multiply those obtained for the unit loading by the magnitude of the actual boundary load. In other words, the stress diagrams in Fig. 9 are influence lines in the usual engineering sense.

Finally, if the external boundaries are loaded with a normal compressive force P_0 and the perimeter of the hole with a normal compressive force, P_1, the solution is obtained by multiplying the stresses σ' and τ' by P_0 and the stresses σ'' and τ'' by P_1, and then superimposing the results.

It is to be noted that the stresses σ' and τ' are due to a unit compression on the entire external boundary $\alpha = 0$. This includes both the plane surface of the foundation and the infinite boundaries. In many practical applications it is desirable to remove all or part of the load on the infinite vertical boundaries. For this purpose the theoretical solution by Mr. Jeffery [11] (mentioned parenthetically by Mr. Mindlin in the text following Equation (36)), is applicable. However, the author has raised a doubt about the strict correctness of Mr. Jeffery's application of his general bipolar solution to this case; therefore the writer has conducted a series of photoelastic experiments which will serve both a practical purpose and as an experimental check on Mr. Jeffery's theoretical results.

Photoelastic Study.—In the photoelastic study of Mr. Jeffery's problem, of course, it was impossible to use a bakelite sheet of infinite dimensions. It is believed that the results obtained by using a plate of finite dimensions give valid results when the diameter of the hole and the distance from the free edge are small in comparison with the over-all dimensions of the model, in accordance with Saint-Venant's principle.

The model was constructed in rectangular form of bakelite, 0.5 in. thick, with vertical boundaries 2.75 in. wide by 4.62 in. long. A quarter-inch hole was drilled near one free edge of the model, such that $\frac{d}{r}$ was 6 (d is the distance from the center of the hole to the straight boundary and r is the radius of the hole). When the experiment was completed for the case $\frac{d}{r} = 6.0$, the model was reduced in width successively so that the ratio $\frac{d}{r}$ was equal to 5.0, 4.0, 3.0, 2.0, 1.0 and 1.5. The normal load on the lateral boundaries was maintained at a constant intensity of 1 000 lb per sq in.

The photoelastic interferometer [30] was used to measure the individual principal stresses along the shortest straight line connecting the straight edge of the model with the hole. The boundary stresses around the hole and along the free edge were obtained directly from the isochromatic photographs.[29]

---

[30] "Direct Optical Measurement of Individual Principal Stresses," by J. H. A. Brahtz and John Soehrens, Jun. Am. Soc. C. E., *Journal of Applied Physics*, Vol. 10, No. 4, April, 1939.

For example, the stresses along these lines for $\frac{d}{r} = 1.5$ are shown in Fig. 10, and the isochromatic photographs for $\frac{d}{r} = 1.5$ and 6.0 are shown in Fig. 11. In these the calibration of principal stresses along a free boundary is 0.173 p per fringe, in which p is the intensity of loading on the vertical boundaries and is assumed equal to unity. The probable error in the experimental stresses is ± 5 per cent. The calibration for maximum shears, of course, would be 0.0865 p. Note that the stresses along the straight boundary are compression throughout.

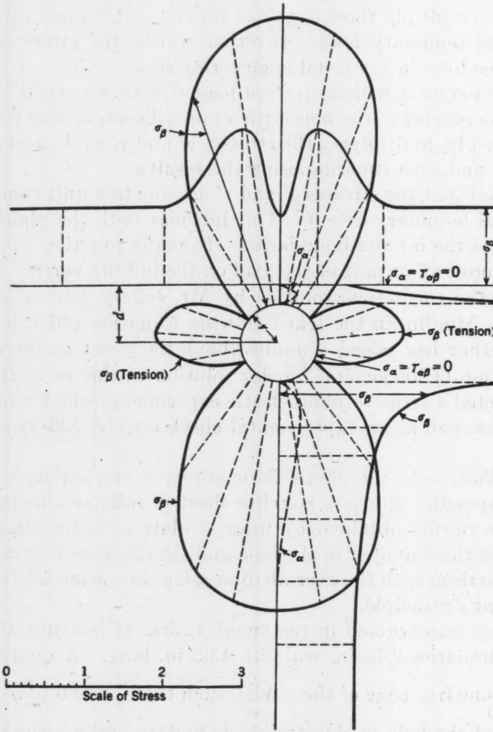


FIG. 10.—UNIT NORMAL COMPRESSION ON VERTICAL BOUNDARIES AT INFINITY; $\frac{d}{r} = 1.5$ (ALL STRESSES COMPRESSION EXCEPT AS NOTED)

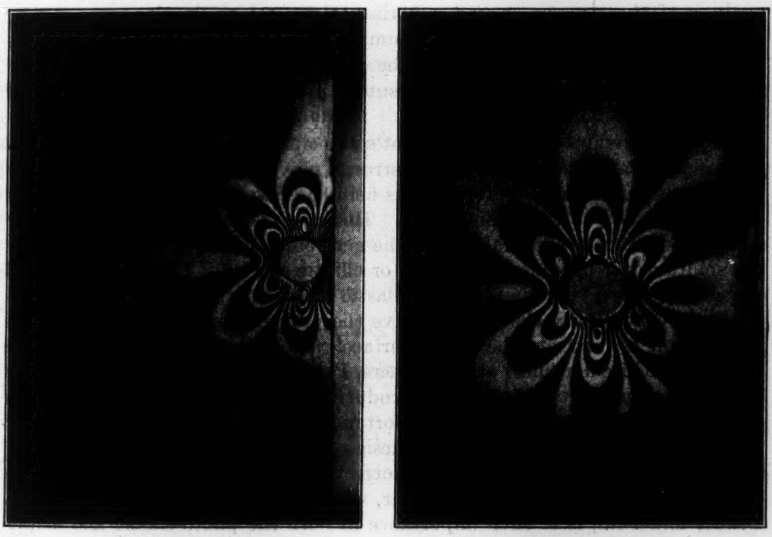
The stresses plotted as in Fig. 10 for unit end loading of the vertical infinite boundaries, in connection with the stresses plotted as in Fig. 9 and combined with the author's results, permit of the complete stress determination for various boundary loading and body forces.

The theoretical results of the paper may be used with sufficient accuracy for civil engineering purposes to estimate the stress conditions around vertical shafts and inspection galleries near the faces of the dam, and pressure pipes running through the dam. These problems have been treated elsewhere[31, 32] under the assumption that the openings were far removed from the faces, whereas the present theory permits the opening to come as close to the faces as practical considerations will permit. In this application of the theory, it is customary first to compute the principal stresses at the center of the opening, as if the opening did not exist, and then apply these principal stresses as normal boundary loading far removed from the opening and compute the stresses in the vicinity of the opening by the present theory.



(a) $\frac{d}{r} = 1.5$ (b) $\frac{d}{r} = 6.0$

FIG. 11.—ISOCHROMATIC PHOTOGRAPHS; MAXIMUM SHEAR CALIBRATION 0.0865 p PER FRINGE; VERTICAL LOAD

It is hoped that the author, in his closure, will comment further on the apparent discrepancies in the theoretical and photoelastic results for a plate with an eccentric circular opening and under a uniform traction. This problem is important as it occurs in many forms in practical structures.

Finally, it should be noted that the author's bipolar transformation can be used also for the determination of the liquid pore pressures which may exist in the material surrounding the tunnel and the seepage into the tunnel. The

theory and formulas for these effects may be found in the memorandum[29] as well as the details of the various theoretical and photoelastic studies mentioned and exemplified by the writer.

Acknowledgments.—The writer wishes to express his appreciation to the staff of the photoelastic laboratory and others of the Bureau of Reclamation, Denver, Colo., for their valuable assistance in the preparation of this discussion. Mr. John E. Soehrens, Associate Engineer, Mr. H. B. Phillips, Junior Engineer, and Mr. H. J. Kahm, Engineer Aid, performed the photoelastic experiments. Mr. C. N. Zangar, Assistant Engineer, and Mr. J. R. Bruggeman, were responsible for the mathematical analyses.

RAYMOND D. MINDLIN,[33] ASSOC. M. AM. SOC. C. E. (by letter).—An analysis of the stresses around a horizontal tunnel of circular cross-section, situated in a gravitating elastic medium, is presented in the paper. It shows how the stresses are affected by (1) the proximity of the free upper surface of the medium, (2) a certain range of assumed initial stresses in the medium, and (3) variation of Poisson's ratio.

A result predicted from St. Venant's principle was verified—that is, when the tunnel is far from the surface the stresses may be calculated by considering the tunnel situated in a uniform stress field composed of the principal stresses initially present at the tunnel level. However, even in this comparatively simple case, there are available from the mathematical theory of elasticity only the solutions for openings of circular or elliptic section. Professor Richmond has shown how a very simple photo-elastic experiment, combined with a judicious use of elasticity theory, will solve the problem for any shape as long as the opening is far from the upper surface. In his application to the square section with circular fillets at the corners, Professor Richmond finds that there is an optimum fillet radius which produces a minimum stress concentration factor. This is a result of some importance which might be applied usefully in other fields of stress analysis and design.

Professor Richmond has listed correctly the limitations inherent in his suggestion. One of these in particular, which was also pointed out by Messrs. Brahtz and Feld, is of such importance in both the photo-elastic and mathematical treatments of the tunnel problem that it warrants another repetition. It is that the stresses in the vicinity of the tunnel cannot be predicted, even approximately, without advance information as to the state of initial stress in the medium. This was stated in the original paper when comparing the widely different results obtained for Cases I, II, and III.

Mr. Feld mentions the question of the effect of Poisson's ratio on the stress distribution. As stated in the paper, the reason for the great change in the stresses of Case II when Poisson's ratio is altered is that, in this case, the boundary conditions are functions of Poisson's ratio.

The effect on the stresses of bracing or lining in the tunnel, mentioned by Mr. Feld, can be calculated by the methods of elasticity theory. The effect of grouting pressure can be estimated from Jeffery's solution for the hole under uniform pressure in the semi-infinite plate. The results obtained from this solution are indicated in the first part of the discussion by Mr. Brahtz and are treated in greater detail in the source to which Mr. Brahtz refers.[29]

---

[33] Instr., Dept. of Civ. Eng., Columbia Univ., New York, N. Y.

Mr. Brahtz reveals a very interesting point in his discussion of the problem of the semi-infinite plate with a circular hole near the straight boundary and under uniform stress parallel to the straight boundary. The point in question is whether or not there is a reversal of sign in the stress along the straight edge when the hole is close to this boundary. According to Jeffery's mathematical solution of the problem, there should be reversal of sign for $\frac{d}{r} < 2$. Mr. Brahtz made a photo-elastic experiment with $\frac{d}{r} = 1.5$ and found no reversal of sign, but he noted that the writer had called attention in his paper to an error in Jeffery's solution which prevents comparison with the experimental results.

The writer has corrected Jeffery's solution and finds that Mr. Brahtz's results are partly verified. The corrected solution indicates that there is no reversal of sign along the straight boundary. However, there are some discrepancies between the magnitudes of the stresses obtained in Mr. Brahtz's experiments and those found mathematically. These discrepancies result in percentage errors higher than the 5% estimated by Mr. Brahtz, especially in the regions of low stress. This is to be expected, since a small error in the measurement of phase retardation, while producing a negligible percentage error in regions of high stress, will produce a very large percentage error in regions of low stress.

The writer has calculated the corrected values for Jeffery's problem and has verified them photo-elastically for values of $\frac{d}{r}$ down to 1.1. The details of the results will be presented in another paper.

THE UNIT HYDROGRAPH PRINCIPLE APPLIED TO SMALL WATER-SHEDS

By E. F. Brater,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. Franklin F. Snyder, LeRoy K. Sherman, Raphael G. Kazmann, Waldo E. Smith, and E. F. Brater.

Synopsis

The unit hydrograph principle was first presented in 1932 by LeRoy K. Sherman,[2] M. Am. Soc. C. E. Since then it has been developed into a usable method for surface run-off analysis. The most notable advance was the introduction of the distribution graph and pluviagraph in 1934 by Merrill M. Bernard,[3] M. Am. Soc. C. E.

Although the method has become quite generally accepted, the engineers and hydrologists who have made special studies in this field have suggested that further research be conducted to determine, more definitely, the limitations in the application of the unit hydrograph. One of the unsettled issues is the question of its usefulness on small streams.

It is hoped that the present investigation will provide a better understanding of the natural phenomena involved in the production of a unit hydrograph. The paper demonstrates that the unit hydrograph principle may be applied to small water-sheds, and that the distribution graphs and pluviagraphs are valuable tools for the analysis of surface run-off. The study further indicates that the unit hydrograph method is one of the best practical devices for predicting flood flows.

Introduction

The investigation described in this paper was conducted to determine whether the unit hydrograph principle is applicable to small streams and, if so, to determine its usefulness as a tool in the analysis of surface run-off.

Note.—Published in September, 1939, *Proceedings*.

[3] "An Approach to Determinate Stream Flow," by Merrill M. Bernard, *Proceedings*, Am. Soc. C. E., Vol. 60, January, 1934, pp. 3–18.

The study is based on continuous records of run-off and rainfall taken from twenty-two small water-sheds by the Appalachian Forest Experiment Station.[4] The water-sheds lie in the high rainfall belt of the Southern Appalachians. They vary in area from 4.24 acres to 1 876.7 acres, and in cover type, from old-growth forest to complete denudation.

The first part of the investigation was devoted to the selection of unit hydrographs and the preparation of distribution graphs on the twenty-two streams. The method of selecting the unit hydrographs from the discharge records of the water-sheds is presented, with a general consideration of the principles involved in the selection. The various factors to be considered in the separation of surface run-off from ground-water flow are discussed, and a method of procedure for making this separation on hydrographs from small streams is suggested. Distribution graphs were derived from each of the unit hydrographs, and the graphs from each stream were superimposed upon one another to permit the selection of a composite distribution graph for the stream. A detailed study was made of the rainfall that produced the unit hydrographs for the purpose of determining more definitely the conditions that govern the formation of such graphs.

The second part of the work consists of some applications of the distribution graphs for the purpose of further testing the adequacy of the theory, and to indicate the value of the unit hydrograph as a tool in the analysis of run-off phenomena. The composite distribution graphs were analyzed for the purpose of disclosing any correlations between the shapes of the distribution graphs, especially the peak percentages and the widths of bases, with the physical characteristics of the water-sheds. The distribution graphs of three of the streams were then utilized in the construction of pluviagraphs for comparison with actual hydrographs of run-off. The pluviagraph studies led logically to a consideration of surface run-off coefficients. Finally, a method is submitted for the use of the unit hydrograph principle as a practical method of predicting surface run-off.

BASIC DATA

The investigation is based on rainfall and discharge records collected continuously for periods varying from two to three years. Fifteen of the twenty-two water-sheds are forested, two are void of all vegetation, and the remainder have varying types of vegetative cover. They are situated in three separate experimental areas, the streams of each group being designated by the name of the experimental area together with their number within the area.

Locations of the Installations.—The first group of seven installations is in or near the Bent Creek Experimental Forest which is about 11 miles south of Asheville, N. C. Four of these are forested, and one is a mixture of forest and adjoining agricultural land, whereas the other two are over-grazed pasture and abandoned farm land. The location of Bent Creek and the other two experimental areas is shown in Fig. 1. Descriptive data concerning all individual water-sheds are given in Table 1, the vegetal cover in each case being as follows:

---

[4] Appalachian Forest Experiment Station, U. S. Forest Service, Department of Agriculture, Asheville, N. C. (see "Engineering Aspects of the Influence of Forests on Mountain Streams," by Richard A. Hertzler, Jun. Am. Soc. C. E., *Civil Engineering*, August, 1939, p. 487).

Stream No.	Description
Bent Creek 1	Forest; oak-chestnut type; a high percentage of old-growth timber; the forested areas were heavily settled and farmed prior to 1900; no large-scale lumbering operations have been undertaken on this area except for cutting and clearing on the individual farms. Scattered areas were burned from time to time, prior to 1926.
Bent Creek 2	Forest; two-thirds of the standing trees, including all non-commercial trees, were cut in the winter of 1930–1931; heavy skidding operations at that time greatly depleted the litter layer.
Bent Creek 3	Over-grazed pasture and abandoned old fields; sheet erosion well advanced.
Bent Creek 4	Approximately 50% forested, and 50% cultivated land and abandoned old fields.
Bent Creek 5 and 6	Forest; second growth of the oak-chestnut type.
Bent Creek 8	Abandoned old fields; eroded.
Copper Basin 1 and 2	Forest of the oak-chestnut type; this region has a relatively thin layer of soil, underlain by shales and sandstone.
Copper Basin 3 and 4	Grass-land; sheet erosion and some gullying in progress.
Copper Basin 5 and 6	No cover; top-soil completely removed and terrain deeply gullied.
Coweeta 1 to 9	The primary vegetation of all the Coweeta watersheds is second-growth forest of the oak-chestnut type, with scattered areas (less than 25% of the whole) of old-growth timber. The entire area was lumbered commercially as long ago as 1919.

Coweeta Experimental Forest (see Table 1(*b*)) is about 15 miles south of Franklin, N. C., and 6 miles north of the Georgia State line. The two larger water-sheds of this group (Stream No. 8 and Stream No. 9) include the entire experimental area. All of the others lie within the boundaries of these two. The entire area is covered with second-growth forest.

The remaining six water-sheds are in the southeast corner of Tennessee, within or near the area known as the Copper Basin (see Table 1(*c*)). This region derives its name from the copper-mining and smelting activities in Copperhill and Ducktown, Tenn., about which the area centers. The Copper Basin consists of approximately 8 sq miles of completely denuded land surrounded by a zone of grass-land the area of which is 22 sq miles. The denudation was started by cutting the larger trees, but the principal damaging factor was the sulfur fumes resulting from the original open roast-heap method of smelting. The denuded area is deeply gullied and all top-soil is washed away. The grass-land has suffered from sheet erosion and is in early stages of gully formation. Two water-sheds were gaged in each of these zones. Two others are located just west of the Copper Basin in the Cherokee National Forest.

Methods of Measurement.—Stream flow was gaged by means of standard sharp-crested weirs, right-angle V-notch weirs being used on the smaller streams and trapezoidal weirs on the larger ones. Heads over the weirs were recorded continuously by float gages. Each weir was set accurately in a concrete dam, which was extended to rock bottom in all cases. Stilling basins behind all the weirs were more than adequate to satisfy requirements for proper contraction of the jet and for reducing the velocity of approach to a negligible quantity. The type of weir used in each case is indicated by footnotes in Table 1.

Rainfall was measured by means of standard Weather Bureau rain gages, with a smaller number of recording gages. There were twenty-seven standard rain gages and five recording gages on the Bent Creek water-sheds, twenty-three standard and six recording gages on the Copper Basin water-sheds, and sixty-three standard and six recording gages on the Coweeta water-sheds. Considering the total area of all the water-sheds, the average area per rain gage was thirty-seven acres. The gages were arranged to give the best possible sample, taking into account aerial distribution, elevation, and aspect. The average precipitation was computed by the Thiessen method.[5]

The Preparation of Unit Hydrographs and Distribution Graphs

The principle underlying the unit hydrograph method may be stated briefly as follows:[6] For any water-shed, the surface run-off resulting from a unit storm is distributed, according to time, in a characteristic manner, and this distribution is independent of the intensity of the rainfall.

A unit storm is a rain of an intensity sufficient to produce surface run-off which occurs within the period of rise of the hydrograph. The period of rise is the time from the beginning of surface run-off to the occurrence of peak discharge.

Definitions.—Since the terminology that is applied to this phase of hydrology is not entirely uniform, the following terms are defined according to their usage in this paper.

Surface Run-Off.—That portion of the precipitation which reaches the stream by means of overland flow.

Period of Surface Run-Off.—The time intervening between the appearance of surface run-off at the gaging station and the time when all surface run-off has passed the station. The period of surface run-off is equal to the period of overland flow plus the time required for the remaining channel storage, derived from overland flow, to pass the gaging station.

Period of Rise.—The time intervening between the beginning of surface run-off and the occurrence of the peak discharge.

Infiltration Capacity.—The maximum rate at which a given soil, when in a given condition, can absorb falling rain.[7]

Surface Run-Off Coefficient.—The percentage of the total rainfall on a water-shed that appears at the gaging station as surface run-off.

Unit Storm.—Isolated rainfall falling at an intensity greater than the infiltration capacity and having a duration equal to or less than the period of rise.

Unit Hydrograph.—A hydrograph of surface run-off resulting from a unit storm.

[7] "Surface Run-off Phenomena, Part I—Analysis of the Hydrograph," by Robert E. Horton, *Publication 101*, Horton Hydrological Lab., Voorheesville, N. Y.

Distribution Graph.—A graph having a time base equal to that of the unit hydrograph from which it was derived and having ordinates that represent the percentage of total surface run-off that occurs in certain selected equal time intervals. It provides a graphical representation of the characteristic distribution of surface run-off from a water-shed.

Selection of the Unit Hydrographs.—The first step in the preparation of the distribution graphs was the selection of unit hydrographs from the continuous run-off records. The method was to select isolated, clean-cut surface run-off graphs that occurred at a time of low flow (see Fig. 2). If insufficient graphs of this nature were available, those which were affected by small rains before or after the main one were used. In such a case the main graph was separated from its "parasite" after a careful study of the normal rising or receding sides of other surface run-off hydrographs from the same stream.

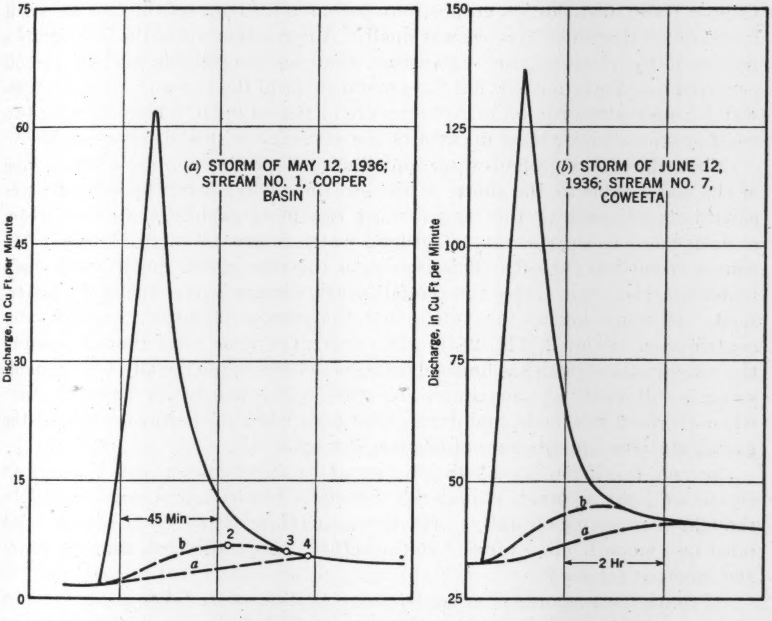

FIG. 2.—TYPICAL HYDROGRAPHS

This procedure was necessitated by a lack of knowledge of the type of rains that would produce unit hydrographs. In the light of the knowledge gained from the work, it is possible to select the unit storms from the rainfall records by selecting intense isolated rains, the duration of which was less than the period of rise indicated by the area and nature of the water-shed. The only advantage of selecting the unit storms from the rainfall records rather than from stream-flow records occurs when continuous stream-flow records in the form of hydrographs are not available.

The Separation of Surface Run-Off from Ground-Water.—The second step in the preparation of the unit hydrographs was the separation of surface run-off from ground-water contribution. Under these ideal conditions (isolated storms occurring at times of low flow) this procedure became relatively simple. The separation was made first as indicated by Base Line *a*, Fig. 2(*a*). A study of the ground-water build-up during rainfall later indicated that for most streams a base, such as Base Line *b*, was more nearly correct. In the case of Stream No. 1, Copper Basin, distribution graphs were prepared for both sets of base lines and it was found that the difference was small. An investigation of the hydrographs produced by rains of such intensities that no appreciable surface run-off occurred has also indicated that the general shape of the line separating ground-water from surface run-off is in the nature of Base Line *b*. The following two considerations lend weight in favor of the accuracy of this observation.

First, the rate of ground-water contribution depends upon the average slope of the water-table at the shores of the stream. Obviously, the ground-water elevations adjacent to the stream must rise more rapidly than the stream elevations to cause the rate of ground-water inflow to increase during the course of surface run-off. This is true in the case of the small water-sheds under consideration, where the rainfall nearly always covers the entire water-shed. It seems logical to assume that the maximum rate of ground-water contribution (Point 2, Fig. 2(*a*)) will occur at a time after the elevation of the water in the stream has finished its rapid decline, while the adjacent ground-water is still nearly at a maximum elevation. This point occurs near the time when overland flow ends, and during that time when the surface run-off at the gaging stations consists only of channel storage.

Second, it is inconceivable that the ground-water discharge could vary in an erratic or jerky manner. Similarly, the effect of channel storage cannot be thought of as ending abruptly. It follows, therefore, that the line of separation must be a smooth curve tangent to the actual hydrograph both where it leaves and where it rejoins it.

If continuous records of ground-water elevations were taken in conjunction with records of water elevation in the stream, it would be possible to determine the exact nature of this line of separation with considerable accuracy.

Although the preceding comment concerns especially the conditions on small water-sheds, the same general line of reasoning may be applied to larger water-sheds. However, in the latter case, unusual conditions may arise which require special consideration. For instance, it frequently happens that rain occurs only in the upper reaches of a water-shed and misses entirely the region where the gaging station is situated. When the stream rises at such a station, there must be a temporary reversal in the ground-water gradient and the ground-water contribution could conceivably be negative for a short interval. Even in this case, the volume of water required in most water-sheds to build up the underground water to the level of the stream would be quite small. Furthermore, a portion of the water flowing in the stream is ground-water contribution from the region in which the rain occurred, and it would be a very extreme case if this volume were not more than sufficient to supply the deficiency in the lower reaches. It can safely be assumed that, in all cases, the line of separation will have a minimum slope of zero and generally will slope upward during the period of overland flow.

On the basis of tests by the Appalachian Forest Experiment Station, thus far, it may be stated with considerable assurance that the line of separation for small water-sheds is a reverse curve of the nature of Base Line *b*, Fig. 2(*a*). The line is quite definitely fixed by the two points of tangency (Points 1 and 3) and by the maximum ordinate (Point 2).

Generally, even in the case of storms producing overlapping unit hydrographs, the point where surface run-off begins (such as Point 1, Fig. 2) is quite definite.

In the case of the hydrograph shown, the point where surface run-off ends (namely, Point 3) was selected because at this point the graph flattens out rather suddenly. Such a point is not always evident and its selection requires considerable judgment. Although this point cannot be chosen definitely, the maximum time that surface run-off continued after the rainfall ended usually may be selected with assurance, as for instance the time from the peak to Point 4, Fig. 2. This information becomes extremely important when applied to complicated hydrographs resulting from a series of rains, in which instance the selection of this point becomes much more difficult. In cases of this nature, studied by the writer, the lengths of base lines determined by different persons have varied by as much as 100 per cent. By utilizing the knowledge gained from the unit hydrograph, this difference would be more of the order of 5 per cent.

The high point (such as Point 2, Fig. 2(*a*)) probably occurs near the end of overland flow, or about half-way between the peak of the hydrograph and the end of surface run-off. Until more quantitative results are available, the height of this point must be a matter of judgment based on a study of the flow characteristics of the particular stream.

The Construction of the Distribution Graphs.—Having separated ground-water from surface run-off, the unit hydrographs are represented by the ordinates between the line of separation and the actual hydrograph. The unit hydrographs thus determined were then divided arbitrarily into time intervals, and the average rate of surface run-off was determined for each interval. These values were totaled and the percentage of the total occurring during each of the periods was computed. The resulting percentages are a numerical representation of the distribution graphs. Time intervals varying from 2.5 min to 30 min were used, the object being to represent the shape of the graph faithfully with a minimum of labor.

It should be noted that the magnitude of the percentages making up a distribution graph depends on the time interval selected. If 7.5-min intervals instead of 15-min intervals were chosen in a given case, it is evident that the percentages would be half as great. Therefore, for the purpose of comparison, all the distribution graphs were converted to a common time interval. For

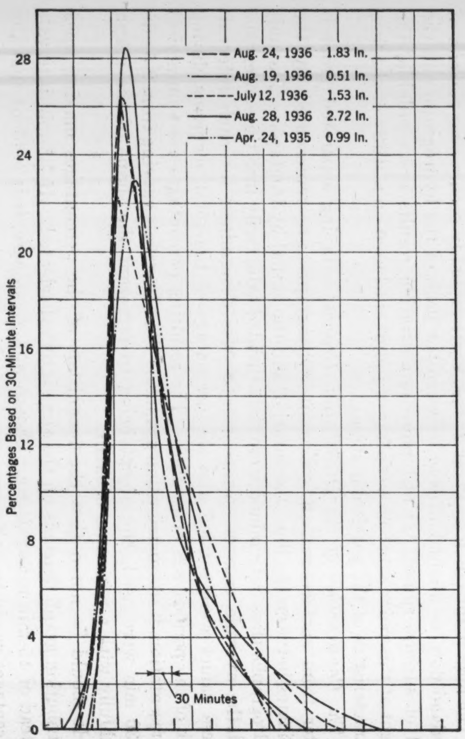

FIG. 3.—DISTRIBUTION GRAPH; STREAM NO. 9, COWEETA WATER-SHED; 1 788 ACRES; FORESTED

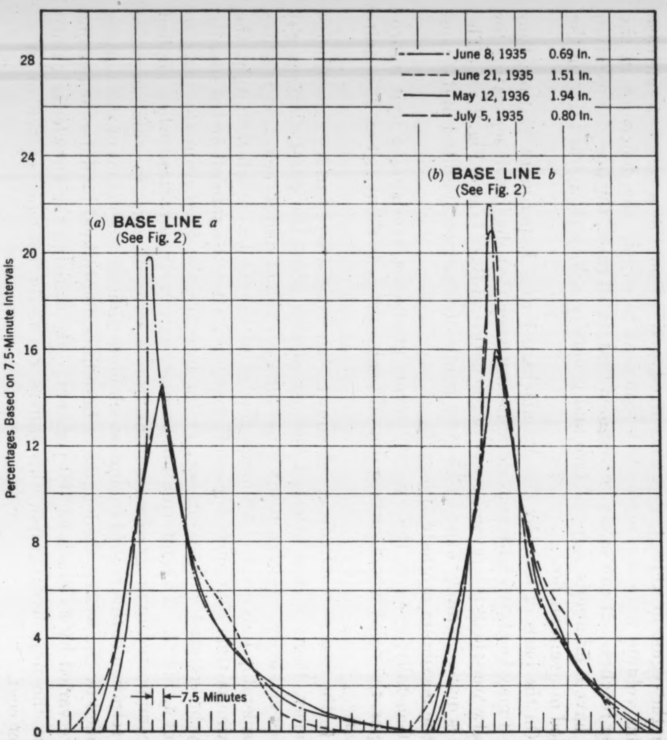

FIG. 4.—DISTRIBUTION GRAPH; STREAM NO. 1, COPPER BASIN WATER-SHED; 19.0 ACRES; FORESTED

example, percentages based on 15-min periods were divided by 6 to reduce the data to a 2.5-min basis. If these results are plotted, they must be spaced at 15-min intervals, since they represent the average 2.5-min interval for a period of 15 min.

The final step was to superimpose all the distribution graphs for each stream as nearly as possible on one another. Figs. 3 and 4 show the resulting clusters of characteristic graphs for two of the streams. A composite distri-

bution graph was then chosen for each case. This was done either by selecting one of the individual graphs as representing an average, or by drawing an average graph through the cluster and taking the percentages from it. The latter process involves a trial-and-error procedure in order to produce a total of 100 per cent. Numerical values of the composite distribution graphs are listed in Table 2.

Characteristics of the Distribution Graphs.—An examination of the twenty-two sets of distribution graphs similar to Figs. 3 and 4 showed that there was a close agreement among the graphs in each group. Furthermore, for any stream, the shapes of the graphs were singularly individualistic. The adherence to the characteristic shape for each of the streams appears to be much closer than in the case of streams draining larger water-sheds.

The rainfall varied considerably within the individual clusters of graphs. For example (see Table 3), unit hydrographs selected for Coweeta 9 were produced by rains varying from 0.51 in. to 2.72 in., those of Coweeta 5 by rains varying from 0.35 in. to 1.69 in., and those of Bent Creek 1 varied from 0.51 in. to 1.44 in.

The actual peaks of the unit hydrographs also varied widely within the individual cluster. For instance, the peak discharges varied from 9 to 95 cu ft per sec in the unit hydrographs used for Coweeta 9 and, in the case of Bent Creek 3, the peak discharge varied from 1.9 to 13.0 cu ft per sec.

The duration of each of the rains used in preparing the distribution graphs and the period of rise for each stream are given in Table 3. The period of rise corresponds approximately to the time of concentration in the so-called rational formula. The latter is usually defined as the time required after the beginning of rainfall for run-off to reach the point of concentration from the most distant point on the water-shed. These studies indicate that a somewhat different conception must be given to this time interval.

A careful study of Table 3 in conjunction with the corresponding distribution graphs will show that the peak discharge appears at approximately the same time after surface run-off starts, regardless of the duration or magnitude of the rainfall. Nearly every set of graphs provides illustrations of this. For

* P = Period of rise.

instance, the period of rise for Stream 9, Coweeta (see Fig. 3), is 75 min. Four of the distribution graphs were produced by rains lasting only from 20 to 42 min. These graphs fall very well in line with the one produced by a much heavier rain which fell during the entire 75 min. On Coweeta 7, rains lasting 30 and 22 min, respectively, produced distribution graphs which coincide with those produced by rains of 60- and 65-min duration. In contrast to these shorter rains, about ten of the rains used were of a longer duration than the period of rise, although, in most cases, the major portion of the rain fell within this period. However, even in the case of the rain of August 23, 1935, on Copper Basin 4 (which lasted five times as long as the period of rise) a definite peak occurred at the same time as those of the other distribution graphs. This evidence may be summarized as follows:

(1) Any rain occurring in a time equal to or less than the period of rise will produce a unit hydrograph;

(2) A rain that lasts somewhat longer than the period of rise but with decreasing intensity also produces a unit hydrograph; and,

(3) There is a tendency for the period of rise to be unaffected even if the rain continues longer at a high intensity.

The foregoing considerations help to trace the sequence of events that constitute the process of surface run-off. This process is believed to be as follows: The first rainfall that occurs at a rate in excess of the infiltration capacity produces surface storage. As rainfall continues the surface water begins to move down the slopes in thin films and tiny streams. Surface tension and friction play an important part at this stage. As these minute rivulets increase in volume, their velocity becomes greater; but their path is tortuous and every small obstruction causes a delay until sufficient head is built up to overcome it. Upon its release, the stream is suddenly speeded on its way again. Each time that two or more of these little streams combine, the water is further accelerated in its down-hill path. It is the culmination of all these small contributions into a final combined accretion to the main stream which produces the ultimate hydrograph. It appears, therefore, that the period of rise has no particular relation to the time required for water to reach the gaging station from the most remote part of the water-shed, since the peak is merely the result of the simultaneous release of the accumulated rainfall from the major portion of the water-shed. The rain that falls near the end of the period begins its overland flow much more readily than that falling earlier, since it falls at a time when all the surface depressions have been filled and into water which is flowing with a relatively high velocity. An increase in the intensity of the rainfall over the minimum required to produce surface run-off increases the total surface run-off but does not materially change the time required to complete the foregoing process.

APPLICATIONS OF THE DISTRIBUTION GRAPH

It has been shown that unit hydrographs exist in, and may be isolated from, the discharge records of small streams. A study of the natural phenomena involved in the formation of a unit hydrograph has thrown light on some phases of the process of surface run-off. In the following studies, the distribution graphs are utilized to test the value of the unit hydrograph principle in surface run-off analysis.

Correlation of the Distribution Graph with Water-Shed Characteristics.—The variety of types and sizes of water-sheds upon which the investigation is based offers an opportunity to relate the characteristics of the distribution graphs with those of the water-sheds. The writer is aware that the exact dimensions of the distribution graphs are partly a matter of personal judgment, especially the widths of bases and the peak percentages. A change in the method of separating base flow from storm flow might change, considerably, the total length of base of the distribution graphs, although it would not materially affect their general shape. Furthermore, in some of the streams, the records may not have been long enough to produce a true unit hydrograph; however, as demonstrated later by the construction of pluviagraphs, the evidence is in favor of their adequacy. In view of the foregoing consideration, the correlations were made to include as much information as possible. None of the graphs contained "average curves." The only averages used were the composite distribution graphs for each stream.

For a comparison of peak discharge, the twenty-two composite distribution graphs were reduced to a 2.5-min basis. The peaks were then plotted in order of magnitude as shown in Fig. 5.

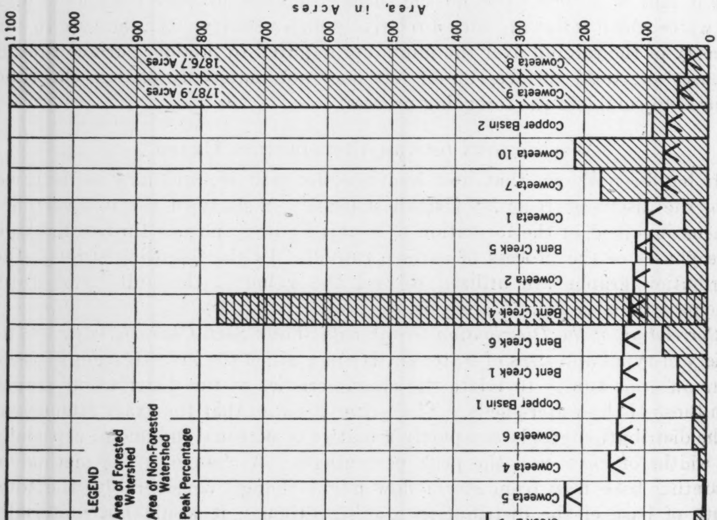

FIG. 5.—RELATION BETWEEN PEAKS OF DISTRIBUTION GRAPHS AND AREAS OF WATER-SHEDS

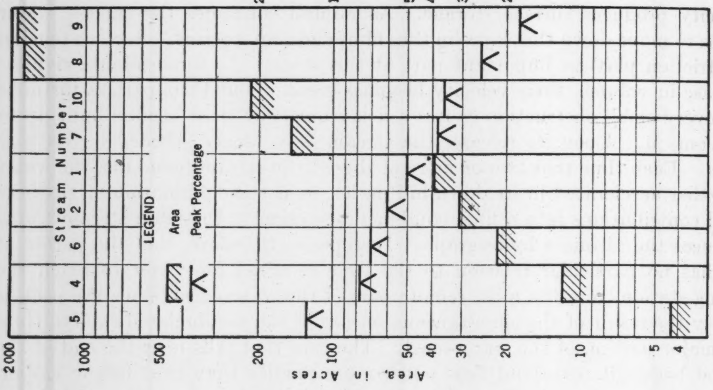

FIG. 6.—RELATION BETWEEN PEAKS OF DISTRIBUTION GRAPHS AND AREAS; COWEETA WATER-SHEDS

That the peak percentage varies according to the area of the water-shed is quite obvious. However, it is the manner in which the variation occurs that is especially interesting. For instance, if the forested water-sheds of the Bent Creek, Coweeta, and Copper Basin areas are considered separately, the agreement between peak percentage and area becomes consistent. That is, from left to right on the graph the areas are constantly increasing. This may be noted by a careful study of Fig. 5; but it is more clearly indicated in Fig. 6, in which only the Coweeta streams are plotted. The greatest peaks for a given area are found at Bent Creek—the smallest at Copper Basin and Coweeta. It is significant that the denuded and grassed areas have peaks much higher than would be indicated by the general trend of the forested areas.

It is interesting to consider, specifically, some of the individual variations from the general trend. For instance, Bent Creek 8 is considerably out of its place, considering merely area and peak. It has the largest area of any of the unforested water-sheds, but has the second highest peak. It is possible that this is due to the fact that this water-shed has nearly a semi-circular shape, with its outlet at the center of the circle, thus permitting all sectors of the water-shed to contribute their run-off simultaneously with practically no delay due to channel storage.

Water-shed 4 on Bent Creek has approximately the position in the graph that one would expect, being about 50% forested and 50% cultivated farmland, abandoned farmland, and cut-over land.

The peak percentage of Stream No. 2, Bent Creek, is considerably above the trend of the other forested water-sheds. Two-thirds of the standing trees were cut from this water-shed in 1930 and 1931, and skidding operations at that time were exceptionally heavy. Furthermore, drainage from approximately 100 yd of roadway discharged into the water-shed. Although the quantity of water entering from this source was not great, it entered in the form of a small stream and followed a fairly narrow and well-defined course to the main stream, discharging into it at a point about 100 ft from the weir. This latter difficulty was eliminated in subsequent records to determine whether the high peak was due to the scarcity of vegetative cover or to the unnatural drainage.

Fig. 7 was prepared to show the variation in the duration of run-off for a unit storm, as indicated by the lengths of bases of the distribution graphs. The bases are plotted using the area, in acres, as the zero ordinate for each graph. The types of water-sheds are indicated by the legend. As is to be expected, the length increases with the area. The sharp difference between the forested and unforested areas is apparent.

Although the individual variations from the general trend (with possible causes as stated previously) are interesting and perhaps significant, the important feature is that there appears to be a general relationship between the dimensions of the distribution graph and the area, and a logical reason for all the deviations. If this is true, the value of distribution graphs as a means of isolating the area factor in the analysis of surface run-off phenomena becomes apparent.

Instead of using a uniform interval of 2.5 min as a percentage basis in the foregoing analysis, it would have been possible, and might at first appear logical, to base the percentage upon a constant portion, say 10%, of the base of the distribution graphs. The effect of selecting the proper length of base lines becomes much more pronounced when this method is used. For instance, the peak percentages based on 2.5-min intervals are 4.0% for Base Line *a* and 4.4% for Base Line *b*, Fig. 2(*a*). Based on an interval equal to 10% of the length of bases, the peak percentages are, respectively, 43.6% and 31.9 per cent. The difference in the first case is 10% and in the latter case about 35% showing that personal judgment in selecting the base line would play a much more important part if the latter method were adopted.

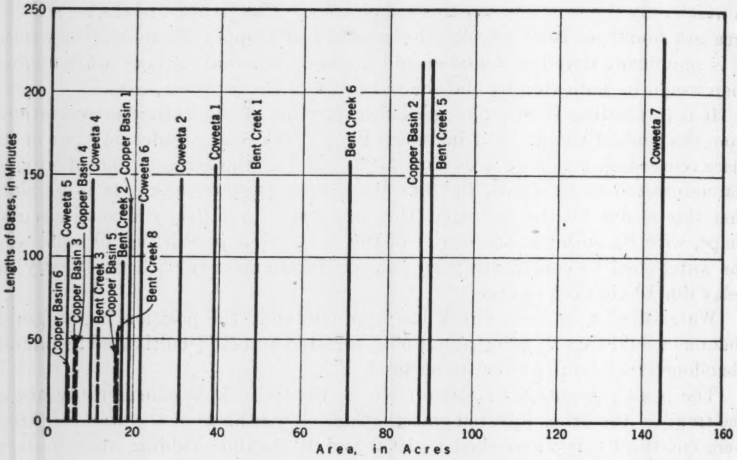

FIG. 7.—RELATION OF WATER-SHED AREAS TO BASES OF DISTRIBUTION GRAPHS

For this reason, and because the peak percentage based on a definite time interval may be translated into rate of surface run-off and therefore has a real practical value, the comparisons were all based on such intervals.

Application of the Pluviagraph.—The pluviagraph is a hydrograph of 100% surface run-off prepared by distributing a rain or a series of rains according to the ordinates of the distribution graphs. It is assumed that each unit storm produces a unit hydrograph, although other subsequent or succeeding rains may produce overlapping graphs. Then, since a distribution graph shows the successive periodic surface run-off contribution of a unit hydrograph, each unit storm must contribute to each time interval, after the beginning of rainfall, a portion determined by the successive percentages of the distribution graph. Only that rainfall which falls at a rate greater than the infiltration capacity becomes surface run-off. Therefore, a coefficient must be applied to the pluviagraph values to produce an actual hydrograph of surface run-off.

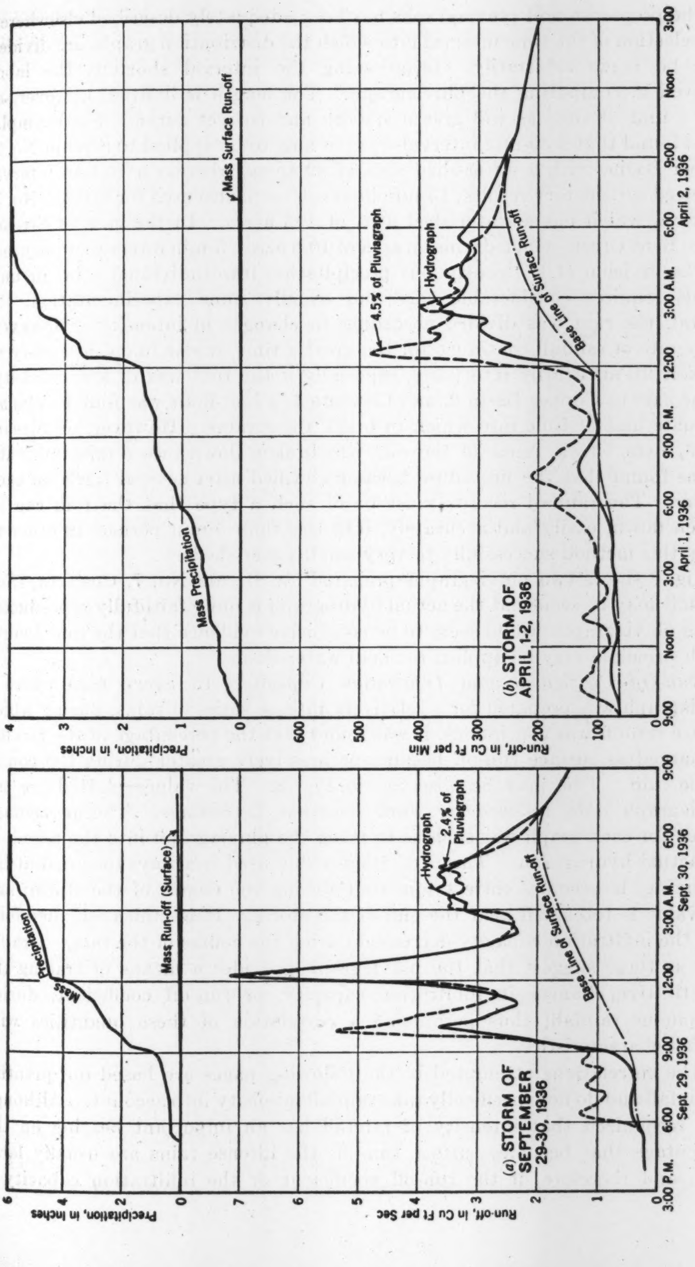

FIG. 8.—PLUVIAGRAPHS FOR TWO STORMS; STREAM NO. 7, COWEETA

The preparation of pluviagraphs has been adequately described elsewhere.[6] The selection of the time interval into which the distribution graphs are divided must be made arbitrarily. Lengthening the interval shortens the labor involved in computing the pluviagraph. The length is limited, however, to such a unit of time as will give a smooth and correct curve. For example, it was found that a 30-min interval was too long to be applied to Stream No. 2, Copper Basin, with a water-shed area of 89 acres, whereas a 15-min interval produced satisfactory results; 15-min intervals were also used for Stream No. 7, Coweeta, which has a water-shed area of 145 acres. In the case of Stream No. 3, Bent Creek, which drains an area of 10.8 acres, 5-min intervals were used.

The division of the continuous precipitation into individual rains or unit storms requires considerable care and usually some experimentation. In general, the rain was divided according to changes in intensity. However, if any rate of rainfall continued for too great a time, it was found necessary to break it up arbitrarily into parts, especially if the rain was of low intensity. In the case of Copper Basin 2, and Coweeta 7, a half-hour was found to be an adequate unit of time into which to break these rains. However, on Stream No. 3, Bent Creek, much of the rain was broken down into 5-min intervals. It was found that the procedure became clarified after several trials on each stream. The rainfall records must be of such a type that the rain can be broken down, easily and accurately, into less than 5-min periods in order to apply this method successfully to very small water-sheds.

Fig. 8 shows two pluviagraphs prepared for Stream No. 7, Coweeta, from which it may be seen that the actual hydrograph is quite faithfully reproduced. These pluviagraphs would seem to be conclusive evidence that the unit hydrograph principle may be applied to small water-sheds.

Run-Off Coefficients and Infiltration Capacity.—In every case where a pluviagraph was prepared for a relatively intense series of rains, during which surface run-off was continuous, it was found that the percentage of the rainfall discharged as surface run-off became progressively greater during the course of the rain. This may be observed in Fig. 8. The values plotted are the pluviagraph data reduced by some constant percentage. The percentage chosen for each graph was such as to bring the pluviagraph into the region of the actual hydrograph. The percentage value used is always too great at the beginning; it becomes correct sometime during the course of the storm; and the value is too small near the end of the storm. It is indicated, therefore, that the infiltration capacity decreased during the course of the rain. Graphs such as these suggest that the pluviagraph provides a means of tracing the quantitative changes in infiltration capacity, or run-off coefficient, during continuous rainfall, thus permitting a correlation of these quantities with rainfall characteristics.

The correlations attempted in the following pages are based on quantity of rainfall and do not specifically take rainfall intensity into account. Although it is recognized that intensity of rainfall has an important bearing on the percentage that becomes surface run-off, the intense rains are usually large ones, and therefore, if the run-off coefficient or the infiltration capacity is correlated with quantity of rainfall, the intensity will be taken into account somewhat. There are several reasons for leaving intensity "out of the picture." In the first place, the determination of mean rainfall intensity for a given series of rains often leads to a distorted result, dependent upon how much of the rain is taken into account. Furthermore, it is difficult to include antecedent rainfall in a correlation involving intensity rather than quantity of rainfall.

In order to determine, quantitatively, the variations in percentage run-off, the percentage which brought the pluviagraph into practical coincidence with the actual hydrograph was determined for each significant peak during the course of surface run-off. This was then related to the quantity of rainfall, which, according to the pluviagraph, had had an opportunity to be converted to run-off at the time when that coefficient was applicable. In Fig. 9, each group of connected points represents such a series of consecutive rains during which surface run-off was continuous.

Four of such series are plotted for Stream No. 2, Copper Basin, in Fig. 9(*a*), together with a number of points from individual rains. It will be seen that there is a definite relationship between accumulated rainfall and percentage of surface run-off, despite the fact that rain intensity and previous saturation are not considered. It will be noted that points plotted for the storm of April 5 and 6, 1936, have higher percentages than for the preceding storm of April 1 and 2, 1936. Undoubtedly, the first storm had an appreciable effect on the second one, and, if this could be taken into account, the two curves would probably come near to coinciding. As the study of soil moisture and its effect upon surface run-off is advanced, this may become possible, but for the present it is more important to know the range within which the coefficients will vary.

Fig. 9(*b*) is a similar graph for Stream No. 7, Coweeta. It will be seen that the trend is noticeably different in this case. The effect of previous saturation noted for the two April storms may be seen again for the same storms on this stream.

Three sets of coefficients in series, and a number of single ones, are plotted for Bent Creek 3, in Fig. 9(*c*). The series of storms occurring on January 7, 1935, is a good example of the rising percentage of surface run-off. At the time Rain No. 1 occurred, 1.72 in. of rainfall had fallen. Since surface run-off was intermittent to this point, the previous rainfall was not considered in plotting the points. The intensity of rainfall was relatively low throughout this rain. The fact that these points lie in a lower percentage range than the main trend would indicate that intensities of rainfall have an important effect in water-sheds of this nature. More evidence of this is found in the series of rains occurring on April 6, 1936. Rain No. 3 of this series was a much less intense shower than Nos. 1 and 2. It may be seen from the graphs that the percentage of surface run-off has dropped back for this rain.

Thus far, no mention has been made of the length of time in which a build-up in the coefficient is sustained after the end of surface run-off. In this connection it is interesting to consider Rain No. 4 of the series just mentioned. In Fig. 9(*c*), Point 4*b* is plotted according to accumulated rainfall, whereas Point 4*a* is plotted according to the rainfall that produced its run-off. A value lying between these two would fall in line with the general trend. A break in the continuity of surface run-off of 1 hr occurred between this rain and Rain No. 3. Although Rain No. 4 was nearly equal in amount and intensity to Rain No. 3, the percentage of surface run-off is much smaller. Surface detention may account for some of this difference, but the following considerations indicate that its effect could not have been great: (1) The slope is relatively great and erosion has advanced to such a stage on this water-shed that actual detention in the form of puddles on the ground must be very slight; and (2) in the several hours intervening between the rains, the relative humidity remained at nearly 100%, so that practically no evaporation occurred. Therefore, the quantity of rainfall previously intercepted and held by the vegetation had not been depleted, and detention from this source may be practically eliminated. The conclusion may be drawn, then, that the infiltration capacity increased considerably in the space of 1 hr despite the 1.60 in. of rainfall immediately preceding.

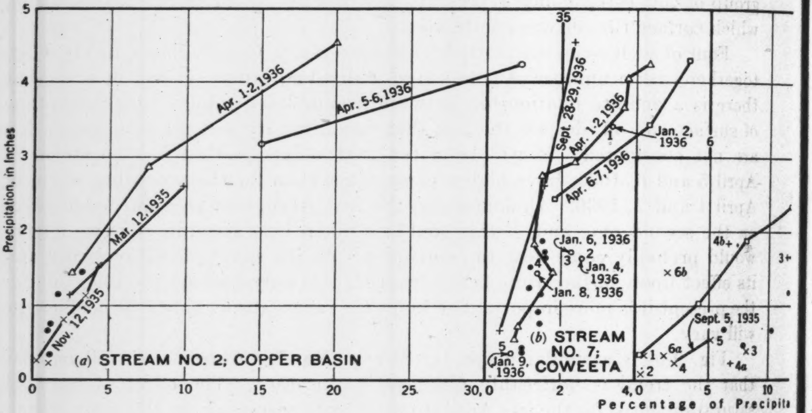

FIG. 9.—RELATION BETWEEN ACCUMULATED

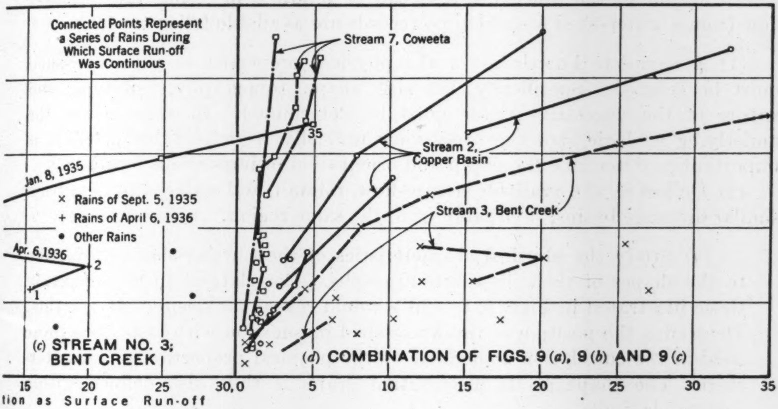
Another illustration is furnished by the rains of September 5, 1936. Surface run-off resulting from these rains was interrupted for periods varying from a half to 1.5 hr between all of the rains except Nos. 4 and 5. For illustration, Point 6*b* was plotted according to accumulated rainfall whereas Point 6*a* was plotted according to the actual rainfall. Since Point 6*a* falls into line with the other points, it appears that the effect upon infiltration capacity of the previous 1.10 in. of rainfall is completely gone in 1.5 hr.

Five heavy rains occurring in the period from April 2 to April 9, 1936, on Coweeta 7 are plotted individually in Fig. 9(*b*). Breaks in the occurrence of surface run-off between the successive storms were 29, 28, 32, and 13 hr in duration, respectively. The amount of each rain is shown by the graph. It may be seen that the points plotted individually fall quite well in line with the general trend, which indicates that these rather heavy rains had little or no effect on the surface run-off coefficient of those following.

The points plotted for each stream in Figs. 9(*a*), 9(*b*), and 9(*c*) are all combined in Fig. 9(*d*). The definitely distinct trends of the points for the three streams are evident, despite the limitations in allowing for intensity of rainfall and previous saturation. If such a series were prepared for a sufficient number of streams, covering a wide enough range in area, cover type, slope, etc., the resulting information would be of value to the practicing engineer, as well as being an important step in the accumulation of a basic knowledge of surface run-off phenomena. It would give the engineer definite limits between which the coefficient could be expected to vary for a given type of water-shed. If he were then able to choose a representative distribution graph, he could predict, far more accurately than he could by the use of any empirical formula, the run-off to be expected from a given quantity of rainfall.



RAINFALL AND PERCENTAGE RUN-OFF

It will be noted that no attempt was made to separate winter and summer rains in the foregoing correlations. A similar study on northern streams would undoubtedly require such a separation. Furthermore, although the indications are that the effect of previous saturation on infiltration capacity is negligible on these water-sheds, it is likely that in other locations this effect may be extremely important.

The value of a series of investigations to determine run-off coefficients under varying conditions cannot be over-estimated. It is extremely desirable that data collected from different sections of the United States be gathered and analyzed to show the effect of soil structure, topography, vegetative cover, temperature, and other water-shed and rainfall factors on the surface run-off coefficient or infiltration capacity.

THE USE OF THE UNIT HYDROGRAPH IN ESTIMATING FLOOD FLOWS

The design of so many structures depends upon a knowledge of the maximum rate of run-off to be expected from a water-shed that any method that will give a more dependable determination of this quantity must be of inestimable value to the engineering profession. The unit hydrograph method possesses several advantages over other methods usually employed for this purpose. First, this method permits the engineer to estimate not merely the peak discharge, but the entire hydrograph of run-off. Second, the peak may be determined for any desired time interval. It thus provides a flexibility that is not provided by any empirical formula. Third, the quantities involved in computation by this method have physical conceptions which are familiar to the engineer. No empirical formulas with vaguely defined constants are involved; the physical characteristics of the water-shed have a straight-forward bearing on the computations. Finally, the method lends itself easily to the experimental determination of the quantities involved—namely, percentage of rainfall appearing as surface run-off and the shape of the distribution graph.

An outline of the procedure that can be followed in estimating the flood flow from a water-shed for which no records are available follows:

(1) A complete knowledge of the physical properties of the water-shed must be secured. Specifically, the size, shape, topography, soil type, and nature of the vegetative cover must be determined. In areas where the underlying geologic structure may vary radically from place to place, it is important to determine the depth and orientation of impervious strata.

(2) Collect all the available stream-flow, rainfall, and water-shed data from similar drainage basins, preferably from the same region.

(*a*) Study the physical characteristics of these water-sheds in relation to the shapes of their distribution graphs. Correlations in the nature of those illustrated in Figs. 5, 6, and 7 would reveal the desired information. Determine the position of the water-shed in question with respect to those used in the correlation as defined by the physical properties of the water-shed. The shape of its distribution graph is thus also defined within reasonable limits.

(*b*) Determine the range of variation of run-off coefficients. The accumulation of all the available data in graphical form as illustrated in Fig. 9(*d*) would show the variations of this coefficient with rainfall and would permit the selection of a maximum value.

(3) Determine the maximum storm that has occurred in the region which might reasonably be expected to occur on the water-shed being studied. Transpose this rainfall upon the water-shed and compute the volume of water applied to the water-shed.

(4) The portion of this volume that will appear as surface run-off may be computed by applying the coefficient determined in Item (2*b*). The hydrograph of surface run-off may now be constructed by apportioning this quantity according to the figures of the distribution graph selected in Item (2*a*).

Where flood estimates are to be made on a water-shed for which some records are available, the results may be obtained in a similar manner except that the records on the water-shed itself would be utilized to the fullest extent in the foregoing procedure.

It is evident that the determination of the maximum flood becomes more dependable as the number of available stream-flow and rainfall records increases. A great mass of such data has been collected in the United States, but its usefulness is limited until it is brought together and analyzed in a systematic manner. Furthermore, for very small water-sheds, average daily discharge records of a stream are of little value for any type of stream-flow analysis. It is necessary that records on such streams (and likewise the rainfall records) be continuous, and that they be available as such to permit their utilization in the advancement of the knowledge of stream behavior.

SUMMARY

The preparation of unit hydrographs and distribution graphs for twenty-two small streams and a study of their relation to the corresponding rainfall and water-shed characteristics have served to reveal some of the natural phenomena involved in the process of surface run-off as well as to point out the usefulness of the unit hydrograph principle in flood-flow prediction. The results are summarized as follows:

(1) Unit hydrographs are produced on small streams and may be readily selected from continuous run-off records;

(2) The ground-water contribution may be separated from the surface run-off with considerable assurance in the case of hydrographs resulting from isolated rains;

(3) The unit hydrograph is an important aid in the separation of ground-water contribution from surface run-off in the case of a complex hydrograph produced by a series of rains;

(4) Any rain that is sufficiently intense to produce surface run-off will produce a unit hydrograph if its duration is equal to, or less than, the period of rise;

(5) The period of rise is a function of the water-shed characteristics and is the time required for the major portion of the water-shed to release its accumulated rainfall load;

(6) There is a definite correlation between the shape of the distribution graphs and the water-shed characteristics;

(7) The reproduction of known flood hydrographs by the use of the pluviagraph provides a method of determining the variation of run-off coefficient or infiltration capacity on a water-shed throughout the period of surface run-off; and,

(8) The unit hydrograph principle provides a fundamentally sound method of predicting surface run-off.

The study has indicated certain lines of investigation that should be conducted to strengthen some features of the unit hydrograph principle and to provide a background of experimental data upon which to base its application in flood-flow prediction. The studies which it is believed would be most fruitful are:

(*a*) An intensive examination of the variations in stream levels and adjacent water-table levels during the course of surface run-off to provide a dependable basis for separating ground-water flow from surface run-off. An exhaustive study on only a few water-sheds would provide data upon which to base the separation in other cases.

(*b*) A study to determine whether a composite or average depletion curve may be used to estimate a hydrograph of run-off during intervals between rains.

(*c*) An investigation to determine the influence of rainfall and water-shed characteristics upon surface run-off coefficients. (Such a study should attempt to isolate and show the effect of various factors such as size, shape, and slope of the water-shed, vegetative cover, cultivation, air temperature, duration and intensity of rainfall, antecedent rainfall, etc. The results would provide a basis for estimating the coefficients in cases where no discharge or rainfall records are available, and would indicate how changes on the surface of the water-shed would influence run-off.)

(*d*) The preparation and systematic analysis of distribution graphs from a large number of streams showing variations in the shapes of the graphs with relation to water-shed characteristics. The knowledge provided by such an investigation in conjunction with a known surface run-off coefficient would permit the construction of flood hydrographs on streams where no discharge records are available.

ACKNOWLEDGMENTS

In its original form, this paper was a thesis presented to the University of Michigan, in 1937, in partial fulfillment of the requirements for the degree of Doctor of Philosophy. The work was first revised under the direction of members of the Department of Civil Engineering, with the special aim of making it a useful contribution to engineering literature. The study is based on unpublished records of rainfall and stream flow gathered by the Appalachian Forest Experiment Station, U. S. Forest Service, with which the writer was formerly associated.

DISCUSSION

Franklin F. Snyder,[8] Jun. Am. Soc. C. E. (by letter).—The usefulness of the unit hydrograph principle in analyzing rainfall and run-off records from small water-sheds is well illustrated in this paper. The author fills the gap, with respect to size of area to which the procedure is applicable, from the city block as demonstrated by W. W. Horner, M. Am. Soc. C. E., and F. L. Flynt, Assoc. M. Am. Soc. C. E.,[9] to drainage areas of several hundred square miles, and larger, as demonstrated by other investigators. Although the paper is quite complete, the writer would like to discuss several items with the hope of increasing the value of the paper as a guide for further studies.

The author has established a procedure for separating ground-water and surface run-off and apparently has been able to ignore the occurrence (if any) of sub-surface storm flow. On larger basins the unit hydrograph crests for large floods are frequently higher than the crest values obtained for small floods, and this is due in part to the difficulties encountered in handling true surface run-off, sub-surface storm flow, and ground-water flow.

From the statements on the separation of surface run-off from ground-water, it appears that the author's procedure includes, with the ground-water discharge, most of the sub-surface storm flow which has entered the surface channels within the confines of the basin. If this could be done for floods and basins of all sizes, it would eliminate the need to consider sub-surface storm flow in connection with unit hydrographs. Since sub-surface storm flow would become effective at the gaging stations shortly after the beginning of run-off, the inclusion of the former with run-off from the ground-water zone would explain the author's conclusion that the rate of ground-water contribution increases as soon as run-off begins.

The writer believes it possible that for a short period of time the ground-water discharge may actually decrease at a greater rate following the occurrence of run-off than before. At some time near the occurrence of crest discharge the ground-water discharge begins to increase and then probably follows a trend similar to that described in the paper. As shown by Mr. Brater, the actual transition would be smooth, regardless of its exact course. However, in practical applications, the separation can perhaps be made more consistent for application to different basins by the use of several straight lines rather than a curved line.

The author has concluded that the period of rise of a unit hydrograph is independent of the duration of rainfall so long as the duration of rainfall does not exceed the period of rise. This is contrary to results obtained from larger drainage basins, and there are several indications that it may be erroneous for the water-sheds under discussion.

There is usually a period at the beginning of rainfall during which no run-off occurs, and the rainfall in this interval is often referred to as initial loss. The duration of initial loss may vary considerably for different storms, especially in summer. The duration of initial loss should be subtracted from the duration of the storm to obtain the duration of the surface run-off producing rain. The latter period of time is the duration of rainfall that should be compared with the period of rise of the resulting discharge graph.

[9] "Relation Between Rainfall and Run-Off from Small Urban Areas," by W. W. Horner and F. L Flynt, *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 140.

Although the writer's experience has indicated that values of initial loss are usually smaller in the Southern Appalachians than for areas farther north, it is believed that such an adjustment to the values of rainfall duration in Table 3 would reveal a closer relation between duration of surface run-off producing rain and period of rise.

Table 4 gives the apparent period of rise, *P*, for the distribution graphs of Figs. 3 and 4 as scaled from the diagrams. There may be some errors and mistakes in these values due to difficulty in distinguishing between the individual graphs. The duration of rainfall, as listed in Table 3, and the value of *P* adopted by the author for each of the two basins is also given. The data show some relation between duration of rainfall and period of rise and it is believed the relation would be more pronounced if periods of initial loss were deducted from the values of duration of rainfall.

TABLE 4.—COMPARISON OF RAINFALL DURATION AND PERIOD OF RISE

Description	STREAM NO. 9; COWEETA; *P* = 75 MIN					STREAM NO. 1; COPPER BASIN; *P* = 38 MIN			
	April 24, 1935	July 12, 1936	August 19, 1936	August 24, 1936	August 28, 1936	June 8, 1935	June 21, 1935	July 5, 1935	May 12, 1936
Duration of rainfall, in minutes	42	35	25	20	75	25	55	30	60
Period of rise (from Figs. 3 and 4), in minutes	103	53	66	77	110	39	58	36	46

The best evidence that the unit of time used with unit hydrographs has an appreciable effect on the results and that the unit should be considerably less than the period of rise is given by the author under the heading "Applications of the Distribution Graph: Application of the Pluviagraph." It is stated that the interval or unit of time for the distribution graph is limited to such a length that the computations will give a smooth and correct curve. These same conditions undoubtedly controlled the break-down of the continuous precipitation into units of time. To accomplish this the author has used a unit of 30 min for Stream No. 2, Copper Basin; yet the period of rise is given as 60 min. The unit of time adopted for Stream No. 7, Coweeta Basin, is 30 min, and the period of rise is 60 min. The only other values given in the paper are for Stream No. 3, Bent Creek, for which the precipitation unit of time is 5 min, and the period of rise is 12 min.

The paper includes a very interesting discussion and illustration of variation in run-off coefficients. In considering the use of the pluviagraph to study the continuous variation in run-off coefficients (assuming the procedure is theoretically correct), it should not be overlooked that the factor obtained by dividing an observed rate of discharge by the corresponding pluviagraph rate is not the true run-off and rainfall ratio for any particular unit period of time except those for the first and last periods of a storm. The coefficient obtained by dividing the discharge rate by the pluviagraph rate is the weighted average of the actual ratios for the various unit periods, parts of the rainfall of which have been combined to obtain that particular pluviagraph rate. This fact does not necessarily impair the usefulness of the ratios between discharge and pluviagraph rates for comparative purposes, but it should not be disregarded when correlating the ratios with actual physical data.

The author has made an excellent analysis of what is undoubtedly a comprehensive collection of data. The availability of data such as those used in the analysis, and those being collected at numerous other experimental areas, suggests that it may not be long before the oft-heard statement decrying the lack of data must be replaced by one emphasizing the need of competent analysis.

LEROY K. SHERMAN,[10] M. AM. SOC. C. E. (by letter).—A careful analysis of unit hydrographs, derived from good rainfall and run-off data, has been made by the author. He has demonstrated conclusively that the unit graph method is applicable to small areas. In his earlier work with the unit graph, the writer dealt with 24-hr total rainfall records. Consistent graphs, which neglected rain intensity and distribution, naturally could not be found unless the area was large enough to furnish time of transit and channel storage sufficient to "iron out" the effects of changing rain patterns. When recording gages are used, as in the author's examples, consistent results will be found on both large and small areas. It has been found that:

(*a*) The unit of time must be less than, and preferably a fraction of, any concentration period; and

(*b*) The unit graph, or the percentage distribution graph, on the larger areas, reflects the pattern of effective rainfall. For example: A storm centered on the lower end of the basin gives a relatively high and early peak, and conversely, a storm centered at the upper part of the basin gives a lower peak rate of run-off for the unit graph. Both are correct. In applications for run-off estimates, the type of graph is selected which is best suited to the given rainfall pattern. This gives better results than the average of several derived unit graphs.

On the derivation of base flow, the author's reasoning, for the adoption of the upper line "*b*," seems logical for the particular basins involved. It is assumed that the author has located Point 4, on the tail of the hydrograph, by actual field observation. That is, Point 4 is the observed time when all material overland flow into the stream has ceased. The writer is of the opinion that many base flow lines are drawn for flood hydrographs which show too great an increase in base flow during the period of surface run-off. Many cases have been found in which the base flow was actually negative. This is due to bank storage of water by infiltration at overbank or high stages of the stream.

---

[10] Cons. Engr., Chicago, Ill.

Before ground-water outflow can increase under high river stages, the infiltration or bank storage must become sufficient to raise the ground-water table. The correct method of solving the problem on an experimental area such as this is, as the author suggests, to have observation wells placed along the bank of the stream for measurement of the ground-water outflow profile.

Mr. Brater has made a careful study of run-off coefficients. This study would have been more useful had he applied his work to infiltration capacity instead of run-off coefficients. Run-off has no definite relation to rainfall, since it is rainfall minus infiltration and other losses. Considerable study and investigation have been made on infiltration capacities and loss rates.[11] The time has come already when such loss rates can, and are, being used in engineering practice for estimating run-off from rainfall. The use of these infiltration capacities or loss rates gives far more accurate results than can be obtained by the most qualified hydrologists in estimating, or guessing, at the coefficient of run-off. There is no run-off unless the rainfall has an intensity greater than the infiltration capacity of the soil. The writer considers it a fundamental mistake to "leave intensity out of the picture." The author is adhering to an old procedure which is fundamentally erroneous and rapidly becoming obsolete.

As an illustration of the infiltration method, Table 5 has been compiled from data furnished by the author. The average infiltration capacity in this table was computed by the direct method, which is premised on the fact that the volume of rain excess is practically equal to the volume of observed surface run-off. Note the consistent decrease in infiltration capacity with duration of effective rainfall. The absorptive capacity of the initially dry soil is greater than the more saturated soil. The average infiltration capacity, following excess rain of more than one or two hours duration, will be only a little greater than the ultimate infiltration capacity.

TABLE 5.—AVERAGE INFILTRATION CAPACITIES

Basin	Date of storm	Average infiltration capacity, in inches per hour	Duration of effective rain, in minutes	Reference
Coweeta 7*a*	6/12/36	2.35 −	25	Fig. 2 (*b*)
Coweeta 7*b*	6/12/36	2.35 +	25	Fig. 2
Coweeta 7	4/ 1/36	2.76	10	Fig. 8 (*b*)
Coweeta 7	9/29/36	2.10	40	Fig. 8 (*a*)

When applying ultimate infiltration capacity to given rainfall, for the purpose of deriving the volume of run-off, it is frequently desirable to know the initial loss rates. The writer is of the opinion that the author's procedure of utilizing the pluviagraph (Fig. 8) to determine variation in run-off percentages can also be used to determine the changes in initial loss rates.

It is pertinent to note that the forested basins used by the author represent an extreme limit of low run-off and high infiltration capacity. This is illustrated by the following derived ultimate infiltration capacities:

---

[11] "Surface Runoff Phenomena," by R. E. Horton, M. Am. Soc. C. E., *Bulletin* 101, Voorheesville, N. Y.; also *Transactions*, Am. Geophysical Union, 1936, p. 302; 1937, p. 371; and 1938, pp. 430–436.

Place	Ultimate infiltration capacities, in inches per hour
Bethany, Mo.	0.15
Illinois	0.10–0.30
Industry, Ohio	0.16
Red River Basin, Okla.	0.21–0.25
North Concho Basin, Tex.	0.30
Lincoln, Nebr.	1.00
Colorado Springs, Colo.	2.00
Coweeta 7, N. C.	2.10
Copper Basin, No. 1, N. C.	3.00 ±

The flat lines of "mass surface run-off" in Fig. 8 indicate the high rate of infiltration on Coweeta No. 7. The writer has replotted the mass run-off for the storm of September 29, 1936, with an expanded vertical scale. This graph shows clearly the relation of run-off to the intensities of rain in excess of infiltration capacity.

RAPHAEL G. KAZMANN,[12] JUN. AM. SOC. C. E. (by letter).—A secondary conclusion advanced in this interesting paper is worthy of some attention. After describing two consecutive rains which followed one another closely, Mr. Brater states (heading, "Applications of the Distribution Graph: Run-Off Coefficients and Infiltration Capacity"), "The conclusion may be drawn, then, that the infiltration capacity increased considerably in the space of 1 hr despite the 1.60 in. of rainfall immediately preceding." This conclusion was based on the data from Bent Creek 3 which indicated that the run-off from Rain No. 4 was about one-half the run-off which resulted from Rain No. 3, although the two rains were "nearly equal in amount and intensity." The question may be raised logically: Can the infiltration capacity of a water-shed be increased by saturating it?

Admittedly, circumstances are conceivable under which such a phenomenon might occur: For example, the presence of a top layer of frozen earth that had been thawed out by the first rain might bring an apparent increase in the infiltration capacity of a water-shed. The same result would occur if the soil were very dry with all the interstices filled with air, if the first rain were a deluge and the second a slower, steadier precipitation. The circumstances would be analogous to those of an air-locked filter. In general, however, experience seems to indicate that the infiltration capacity of a water-shed decreases as the ground becomes more saturated, finally reaching a more or less well-defined minimum.

It is possible, of course, that during the period upon which the author based his conclusion the upper layer of soil was in a frozen or semi-frozen state. If, on the other hand, there was no frost in the ground (April is an in-between month, anyway), there is another possibility implicit in the data collecting methods used in the observations. It lies in the failure to correlate rainfall intensity with the other observations. Mr. Brater states (heading,

---

[12] Junior Hydr. Engr., Ground Water Div., U. S. Geological Survey, Washington, D. C.

"Applications of the Distribution Graph: Run-Off Coefficients and Infiltration Capacity"):

> "The correlations attempted in the following pages are based on quantity of rainfall and do not specifically take rainfall intensity into account. Although it is recognized that intensity of rainfall has an important bearing on the percentage that becomes surface run-off, the intense rains are usually large ones, and therefore, if the run-off coefficient or the infiltration capacity is correlated with quantity of rainfall, the intensity will be taken into account somewhat."

Considering this statement, it is not difficult to surmise how a questionable conclusion concerning increased infiltration capacity might have been deduced. From the rainfall records the quantity of rain and the total time of each of the periods of precipitation was known; but the distribution of the precipitation during these periods was unknown. This was due to the fact that Bent Creek 3 is the smallest of the Bent Creek water-sheds; consequently, since there were not enough recording rain gages to go around (five recording gages *versus* eight water-sheds), it probably did not receive a recording gage.

Probably the first rain was "spotty." Periods of light precipitation alternated irregularly with periods of very intense rainfall. The rain which followed (Rain No. 4) was probably steadier and had fewer periods of intense precipitation. Without recording gages, unless an observer was on the water-shed during the rains, this "fact" would be unknown. By simply dividing the total quantities of precipitation by the periods of time involved, it would appear that the intensities of precipitation were the same, whereas, although average intensities were nearly alike, the actual intensities differed widely. Assuming that the picture sketched is correct, the phenomenon was observed correctly but an incorrect, possibly too hasty, conclusion was drawn. The run-off from the second storm was less, chiefly because the rain, in general, was more evenly distributed and did not come down in spasmodic torrents. This more gradual rainfall gave the soil (eroded and wet though it was) a better chance to accommodate the rain—that is, the rainfall could infiltrate rather than run off on the surface.

WALDO E. SMITH,[13] M. AM. SOC. C. E. (by letter).—The author is to be commended for undertaking the task of determining distribution graphs for twenty-two small water-sheds, attempting to analyze the results, and to demonstrate applications. He has shown that the unit hydrograph principle is applicable to small water-sheds, as well as to large ones, with probably about the same general limitations. The distribution graph has justly become recognized as a handy tool in the kit of the hydrologist; but it should never be overlooked that the method is inherently an approximate one. At all times one should be aware of its shortcomings and inconsistencies, and should not expect too much refinement from it. For instance, it is self-evident that a tank of given size and outlet requires a longer time to become empty if it is full than if it is half full. It is likewise reasonable to expect that a channel full of surface run-off will require a longer time to be drawn down to ground-water flow than a channel only partly full; yet the width of base of the distribution graph is taken as constant for all cases, for a given water-shed. Similar deductions (some compensating to an unknown degree) can be made if ground-water flow is large or small, or if the average stream velocity is small because of overbank flow, or high because the stream is just at bankfull stage.

---

[13] New Philadelphia, Ohio.

The writer is unable to share the author's optimism with regard to the conclusiveness of all of the points stated in the "Summary," particularly the items referring to the relation, or lack of relation, of duration of rainfall to the period of rise. Possibly it is within the inherent accuracy of the method, on small water-sheds, to assume that within the period of rise the duration of rainfall has no effect upon the shape of the resulting hydrograph. For large water-sheds, it is known that this cannot be done. However, to the writer, it does not appear that this assumption can be made for water-sheds of the size under discussion, either in the instance of the author's data or in the case of other similar data that the writer has available. If rainfall of uniform intensity in excess of the infiltration rates continues for the duration of the distribution graph, the period of rise will be found to be about equal to the duration or base of the distribution graph. Perhaps the best test of the validity of the author's assumption on the basis of his data is a consideration of the period of rise. Mr. Brater does not discuss variations in this value, but if one may use values obtained as accurately as possible from the distribution graphs of Figs. 3 and 4(*b*), then Tables 3(*b*) and 3(*c*) may be extended as shown in Table 6 (rearranging in the order of duration of precipitation).

TABLE 6.—SUGGESTED EXTENSION OF TABLES 3(*b*) AND 3(*c*)

Average	....	....	45	Average	....	....	79

For the Copper Basin water-shed there seems to be, almost, a surprizing relation between duration of rainfall and period of rise; but if one examined only the first three of the Coweeta group, one might deduce that the period of rise decreases as the duration of rainfall increases. It would have been interesting if data on mass curves of rainfall and isohyetal maps for these storms and areas had been included in the paper. It is possible that in the case of the 35-min rain on the Coweeta water-shed, the major portion fell early in the period, or perhaps was heavier near the gaging station; but inasmuch as there is nearly a 150% variation from the minimum to the maximum period of rise, it is obviously affected by various factors. The statement concluding "Characteristics of the Distribution Graphs" is an example of the pitfalls into which one can be led by deductive reasoning. It is reasonable and rational, but it does not involve all factors.

In spite of the summary statements on lack of effect of duration of rainfall within the period of rise, under "Application of the Pluviagraph" the author has acknowledged that for the production of the pluviagraph in which "each unit storm produces a unit hydrograph," the precipitation must be divided into periods shorter than the period of rise, and "that a 30-min interval was too long * * * whereas a 15-min interval produced satisfactory results" for Copper Basin 2, with a given period of 60 min. If the author's statement that duration of rainfall within the period of rise has no effect is correct, it should be possible to put the 60-min rainfall into one of the four 15-min periods into which it was divided without effect upon the resulting pluviagraph.

The author has failed to give the lapse of time between the beginning of rainfall and the beginning of the rise. The period of the distribution graph should start with the time at which run-off producing rain starts. Is duration of rainfall, as given, the total time or only that period which presumably produced run-off?

The writer regrets that in engineering and hydrologic literature, distribution graphs are published so often, and that tables of distribution coefficients appear so seldom. The author has set forth coefficients in Table 2, for which he receives hearty approval; but Figs. 3 and 4 use the graph. The writer has found that he can determine a composite from several sets of distribution coefficients in tabular form much more readily than from their graph form, as Table 7 shows. Furthermore, a distribution graph as such has no direct use unless it is in block form as suggested by William T. Collins,[14] Jun. Am. Soc.

[14] "Runoff Distribution Graphs from Precipitation Occurring in More Than One Time Unit," by William T. Collins, *Civil Engineering*, September, 1939, Vol. 9, p. 559.

C. E. Frequently it is plotted as a line connecting the points representing the coefficients, in which case its shape and consequent physical significance are lost.

Fig. 6 is particularly good in demonstrating, within a given region and general set of conditions, the effect of size upon the percentage of peak surface run-off. Fig. 7 is likewise very good; but as the author suggests, the values plotted involve a personal element in the selection of the terminal point of surface run-off and the resultant width of base of the distribution graph. The graph shows the probable trend of the effect of cover, but because so few data are given on factors such as slope and shape, it is not conclusive.

Mr. Brater would have done well to have extended his studies for Fig. 9 one step further and made determinations of infiltration rates. His statement under "Run-Off Coefficients and Infiltration Capacity"—"Graphs such as these suggest that the pluviagraph provides a means of tracing the quantitative changes in infiltration capacity [rate] * * * during continuous rainfall * * *" —is the most noteworthy in the paper. Had the durations of the successive rains (in excess of the infiltration rate) been given, with quantity of rainfall for the same periods, the reader would have been enabled to do this for himself. It is possible that rainfall intensities in some of the cases cited were just in excess of infiltration rates, resulting in the small percentages of run-off noted.

The reference to the shape of the curves of Fig. 9, as a key to the solution of water-shed problems in general, calls to mind a study[15] which showed that coefficients for a given small water-shed, plotted against a quantity of rainfall, scatter over a considerable area.

As for the use of the distribution graph for forecasting flood flows, this is already being done extensively for primary water-sheds and for sub-water-sheds in connection with the operation of the Muskingum water-shed flood-control reservoirs in Ohio, as well as in the Tennessee Valley, the State of Pennsylvania,[16] and elsewhere. Depletion curves of ground-water flow are in use in many offices[17] for determining ground-water flow during periods of run-off, as well as between rains.

On various water-sheds, there is about every conceivable variation of size, slope, soil type, soil profile, soil condition, drainage density, cover, and a real distribution and intensity of rainfall, many of which factors are variable with regard to time as well as with regard to location. These factors are further thrown together in an infinite number of combinations. As far as empirical means are concerned, in addition to the unit graph method and as adjuncts to it, the methods described by R. L. Gregory and C. E. Arnold,[18] Assoc. Members, Am. Soc. C. E., by W. W. Horner, M. Am. Soc. C. E., and F. L. Flynt,[19] Assoc. M. Am. Soc. C. E., and others, are helpful.

Attempts have been made to determine, by analysis of the basin, the influence of each factor; but the great difficulty is that it is not possible to operate (as in a laboratory) to hold all variables constant, except one, and to study the effects of each one in turn. Possibly the best hope for an analytical solution is to plot run-off data with different slopes, soil types, cover, etc., each plot being a relatively homogeneous, small area; and then, after determining the extent to which each factor enters into the heterogeneous water-shed, to integrate, in effect, all of these values. This has been done with success, to the writer's knowledge, to the point that the correct volume or total run-off has been determined closely. The carrying of this flow through the tortuous ways of overland and subsurface flow, and channel and valley storage, to the gaging station is similarly under study with results, so far as the writer is apprised, as yet inconclusive. However, the number of variables involved and the evaluation of these variables even on a small water-shed suggest the difficulty in (and even the uncertainty of) the ultimate solution of the problems involved as suggested by the author. The distribution-graph method, as such, is probably not sufficiently refined to be of service in connection with such a solution if and when it is found. In the meantime, it serves as a very handy tool.

E. F. BRATER,[20] JUN. AM. SOC. C. E. (by letter).—The writer is gratified by the stimulating comments contributed by the various discussers. Some of the discussions provide additional valuable data. Several points of controversial nature were raised and discussed, and the writer wishes to add his views on these several points. In general, it should be said that the analysis was based on a study of twenty-two small southern Appalachian water-sheds. The results reflect the influence of the topography, soil, and vegetation of this region. It must be recognized, therefore, that some of the conclusions may have to be modified if they are to be applied to other localities.

The main purpose of the paper was to study the application of the unit hydrograph to small water-sheds. It seemed desirable to keep the discussion, as far as possible, in terms of well-known and accurately definable quantities. For this reason, run-off coefficients were used instead of the newer conception of infiltration capacity. The run-off coefficient is simply the percentage of a given rain which appears as flood flow in the stream. Its meaning is clear and straightforward and its value may be determined easily, within reasonable limits of accuracy.

Mr. Sherman suggests, however, that the paper would have been more valuable if infiltration capacities had been used. He has computed the infiltration capacity by the direct method for a number of the hydrographs given in the paper and has presented the results along with values from other parts of the United States.

The writer does not question that the infiltration capacity as defined by Robert E. Horton,[7] M. Am. Soc. C. E.—namely, "The maximum rate at which a soil, when in a given condition, can absorb moisture"—is a meaningful and important soil characteristic. It should be recognized, however, that the so-called infiltration capacity computed by the direct method is not the quantity defined by Mr. Horton and does not have any real physical significance. This may be rather forcefully illustrated by considering the three values which Mr. Sherman has obtained for Coweeta 7. It will be shown that there was no overland flow during these three rains, and therefore that the actual infiltration capacity was not reached.

---

[20] Instr., Civ. Eng. Dept., Univ. of Michigan, Ann Arbor, Mich.

The length of stream of Coweeta 7 is 11 100 ft. The width of the flowing stream during a heavy rain varies from about 20 ft to a mere trickle, but the gravelly bed of the stream plus the adjacent banks embraces a strip 20 to 30 ft wide over the length of the stream. Therefore, if all of the flood flow from any given rain can be accounted for by 100% run-off from a strip of land 11 100 ft long and not in excess of 25 to 30 ft wide, it must be concluded that no overland flow occurred. A rainfall on this water-shed of 0.92 in. on June 12, 1936, produced a total flood flow of 6 850 cu ft. This is equal to a volume of water 0.92 in. deep on an area 8.1 ft wide and 11 100 ft long. An 8.1-ft strip barely accounts for the actual area of the flowing stream, so there could not possibly have been any overland flow.

Similarly, rains of 3.98 in. on April 1, 1936, and 5.95 in. on September 29, 1936, produced volumes of flood flow of 50 000 cu ft and 64 500 cu ft, respectively. The widths of 11 100-ft strips from which 100% run-off would have to occur to produce these flood flows are 13.6 and 11.7 ft for these two storms. Here again there was no overland flow.

Since no overland flow occurred, the infiltration rates were simply equal to the rainfall rates, and the infiltration capacity, as defined by Mr. Horton, was not reached; yet Mr. Sherman has computed values of infiltration capacity of 2.35, 2.76, and 2.10 in. per hr, respectively, for these three rains. It is believed that the actual infiltration capacity of Coweeta 7 is more than 5 in. per hr. Overland flow has never been observed from any of the heavily forested areas in this region, except during severe cloudbursts.

It would be highly desirable to be able to compute the actual average infiltration capacity of a water-shed from the rainfall and run-off records. One of the requirements necessary to approach this ideal more closely would be to take into account the part of the water-shed from which 100% run-off occurs. This would include the areas of the lakes and streams as well as all impervious portions of the water-shed. The result of neglecting this factor is illustrated by the foregoing examples. Because of its variable nature, however, it would be difficult to estimate, accurately, the area of 100% run-off. For instance, during a prolonged, heavy rain, not only does the area of the permanent lakes and streams increase, but this area is frequently augmented by additional inundated areas. The error introduced by neglecting impervious areas causes computed values to be too small.

It should also be pointed out that even if the impervious areas and the areas of lakes and streams were carefully taken into account, the infiltration capacity computed by the direct method might still differ considerably from the actual infiltration capacity. This method of computation is based on the assumption that the rainfall excess is equal to the surface run-off. For this assumption to be true, it would be necessary for all the surface detention present at the end of each period of rainfall excess to be transported instantaneously into the flowing stream. This is not true, of course, since most of this surface detention has an additional opportunity of infiltering for periods varying from a few minutes to several hours. Therefore, an error is introduced, the magnitude of which depends on the variation in rainfall intensity. Another error which is inherent in this method of computing infiltration capacity results from the fact that depression storage is included with the total infiltration. All water left standing at the end of rainfall excess, whether it be in tiny puddles or good-sized lakes, is slowly dissipated as evaporation or infiltration. This process may continue for a number of days, and yet the direct method assumes all of this water to have been infiltered during the period of rainfall excess. This factor has little or no effect in the case of the water-sheds discussed in the writer's paper, but may be very important in flat or terraced water-sheds. The errors discussed in this paragraph are compensated for, to some extent, in the case of relatively impervious water-sheds, by residual, low-intensity rainfall which may follow the period of rainfall excess.

The values computed by this method may be very useful quantities for some purposes. It seems highly desirable, however, to avoid calling them infiltration capacities since that implies that they represent the maximum rates at which a given water-shed can absorb rainfall. For instance, they could be called infiltration indexes or rainfall excess indexes.

Mr. Snyder and Mr. Smith ask whether the values of duration of rainfall are corrected for initial lag. The initial lag is small on these streams, since the stream rise begins almost at the beginning of rainfall. The values given are corrected for any minor, low-intensity rainfall that may occur at the beginning and end of the storms. The period given is very nearly equal to the duration of run-off producing rain.

Mr. Sherman points out that the shape of the distribution graph is influenced by the rainfall pattern. Mr. Snyder and Mr. Smith note that the period of rise is not a constant quantity. These are pertinent observations because they emphasize the fact that the unit hydrograph is not a mathematically precise method for predicting the nature of flood flow but simply a workable one, sufficiently accurate for all practical purposes. The original study consisted of an analysis of seventy-eight storms on twenty-two water-sheds. The mean of the individual variations from the average period of rise on all of the water-sheds was about 25 per cent. Part of this variation is due to the presence or absence of a small fillet preceding the main portion of the rising hydrograph. The general shape of the hydrograph is not materially affected thereby.

Mr. Snyder concludes that this variation in the period of rise is due to the variation in the duration of rainfall. The writer indicated in the paper that the period of rise tends to remain constant despite variations in rainfall duration, provided the duration does not greatly exceed the period of rise. Another careful comparison, by the writer, of the period of rise with rainfall duration on all twenty-two of the water-sheds shows no evidence of a direct relationship between the two quantities. Mr. Snyder rightfully cites as evidence of the effect of rainfall duration on the period of rise the statements made by the writer concerning the method of breaking down continuous rainfall records into individual storms for use in reconstructing hydrographs from rainfall data. The paragraph to which Mr. Snyder refers reads in part as follows (see heading "Applications of the Distribution Graph: Application of the Pluviagraph"):

> "In general, the rain was divided according to changes in intensity. However, if any rate of rainfall continued for too great a time, it was found necessary to break it up arbitrarily into parts, especially if the rain was of low intensity. In the case of Copper Basin 2, and Coweeta 7, a half-hour was found to be an adequate unit of time into which to break these rains."

The writer did not, however, intend to imply that periods greater than 30 min would not produce adequate results because periods as long as 130 min were actually used.

Table 8 shows the manner in which the continuous rainfall records were broken down in order to reconstruct the hydrographs presented in Fig. 8. Although it may not be completely clear, due to the small scale of Fig. 8, the intervals chosen correspond to changes in rainfall intensity. The operation was performed without giving any attention to the period of rise. As a result, there is no regularity in the length of time intervals. It may be seen from Table 8 that the intervals vary from 15 min to 135 min. Since the actual hydrographs are quite faithfully reproduced by the reconstructed ones, despite this variation in the length of interval, it appears that the duration of rainfall has only a minor effect on the period of rise. There are other factors which cause the length of the period of rise to vary. The influence of the rainfall pattern was mentioned by Mr. Sherman. Other factors of importance in these small, steep water-sheds are the intensity at which rainfall begins, and the direction of approach of the rainstorm.

TABLE 8.—MANNER IN WHICH TWO CONTINUOUS RAINS WERE BROKEN DOWN FOR THE APPLICATION OF THE DISTRIBUTION GRAPH

(*a*) STORM OF APRIL 1 AND 2, 1936 (INTERVALS FROM 9:30 A.M. TO 5:00 A.M.)						(*b*) STORM OF SEPTEMBER 29 AND 30, 1936 (INTERVALS FROM 5:15 P.M. TO 4:15 A.M.)

7:45–10:00	135	0.11	....	....	....	....	....	....

Mr. Smith isolates the following phrases as evidence of the relationship between duration of rainfall, within the period of rise, and the length of the period of rise: "that a 30-min interval was too long * * * whereas a 15-min interval produced satisfactory results." It is only necessary to read, in its entirety, the paragraph from which this quotation was taken to realize that the time interval referred to is simply the result of the number of divisions into which the unit hydrograph was separated, arbitrarily, in order to compute the distribution graph percentages. In reconstructing a hydrograph from rainfall data, these percentages are applied to the total rainfall to determine the portion contributed to stream flow in each corresponding interval. These portions are correctly plotted as blocks having a width equal to the time interval and height equal to the average rate of flow necessary to produce the given quantity of run-off. In order to construct a smooth curve through the tops of these blocks, they must be made reasonably numerous, especially when two or more of such unit hydrographs are superimposed upon one another. There can be no connection between this purely mechanical or drafting-board procedure and the period of rise of the unit hydrograph.

Mr. Smith makes the following statement in his discussion: "If rainfall of uniform intensity in excess of the infiltration rates continues for the duration of the distribution graph, the period of rise will be found to be about equal to the duration or base of the distribution graph." This statement is not consistent with the meaning of the period of rise as used by the writer. The hydrograph described by Mr. Smith is the combination of two or more unit hydrographs. Therefore, the rising part of the hydrograph consists of portions of two or more periods of rise, and should not be referred to as the period of rise.

Mr. Kazmann states that a decrease in run-off coefficient in the second of two consecutive rains on Bent Creek 3 might have been due to variations in rainfall intensity. The mass diagrams of rainfall for the two rains are quite similar; therefore, it is believed that the dry period of 1 hr which separated the rains permitted the soil to regain some of its capacity for the absorption of water.

TENSION TESTS OF LARGE RIVETED JOINTS

By Raymond E. Davis,[1] and Glenn B. Woodruff,[2] Members, Am. Soc. C. E., and Harmer E. Davis,[3] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Charles F. Goodrich, Frederick P. Shearwood, Jonathan Jones, C. C. Winter, W. M. Wilson, J. M. Garrelts, A. E. Richard De Jonge, E. C. Hartmann and Marshall Holt, and Raymond E. Davis, Glenn B. Woodruff, and Harmer E. Davis.

Synopsis

An extensive series of tests on large riveted joints is described in this paper, including variations in length, type of splice, plate and rivet steel, pitch, and rivet pattern. The paper discloses the behavior of the various parts under load and provides information bearing on design practices. It was found that the usual assumption of equal distribution of load among rivets is satisfactory for design purposes, regardless of length of joint; and, that joints having as many rivets in the end row as in interior rows are as efficient as corresponding joints in which the net section is supposedly protected by using fewer rivets in the end row.

Introduction

The specifications commonly followed in the design of structural riveted connections are based largely on tests made at Cornell University, at Ithaca, N. Y., in 1904.[4] The joints tested at that time were relatively small, having a maximum of nine rivets in either end, and were made of softer plate, and rivet, steels than those now used even for ordinary bridges and buildings. Tests on joints fabricated with nickel-steel plates and rivets were conducted at the University of Illinois, at Urbana, Ill., in 1911;[5] but, again, there were no more than nine rivets in either end of the joint. Tests involving a larger

number of rivets have been confined almost entirely to short joints of the type used in ship, and tank, construction.[6, 7] Experimental data on the behavior of long joints are rare, although theoretical analysis indicates that increasing the number of transverse rivet rows in each end above, say, five results in lower efficiency.

In connection with the design and construction of the San Francisco-Oakland Bay Bridge, it was found possible, in 1934, to begin two groups of tests with the object of securing information on the behavior of long riveted joints containing carbon and alloy steels and on related problems. One group, consisting of fatigue tests of relatively small joints, was conducted at the University of Illinois.[8] The other group, comprising static tension tests of large joints, was conducted at the University of California; these tests are described herein.

The program of static tension tests was planned to secure information on the following points: (1) The strength of large joints containing as many as twenty-eight transverse rows of rivets; (2) The relative behavior of joints having rivets of carbon or manganese steel; (3) The relative behavior of joints having plates of carbon, silicon, or nickel steel; (4) The relative merit of butt and shingle splices; (5) The partition of load among the transverse rows of rivets; (6) The effective net section of riveted plates; (7) Slip phenomena in large joints; and, (8) The proper design relation between tensile stress in plates and shearing stress in rivets. Throughout the tests, effort was made to secure data as to the action of the joints within the working range.

The abbreviation "kip" used throughout this paper denotes "kilo-pounds"; that is, 1 000 lb.

The Action of Riveted Joints

As an aid to the interpretation of test results, it is desirable to review certain general concepts of the action of riveted joints. These views are derived in part from theoretical considerations and in part from the results of these tests.

If perfect fabrication could be attained, the following conditions would exist: (*a*) Plates absolutely flat; (*b*) faying surfaces in contact at time of riveting; (*c*) holes matched perfectly; (*d*) at time of driving, holes completely filled by rivets; and (*e*) after cooling, rivets concentric with holes, with annular space around each rivet. During cooling, owing to the effort of the rivets to contract longitudinally against the restraint of the plates, tension is developed in the shank of the rivets. Lateral contraction of the rivet shank is caused in part by thermal contraction and in part by the Poisson-ratio effect due to rivet tension. The pressure between the plates caused by rivet tension results in a frictional resistance of the plates against slipping.

The behavior, under load, of a perfectly fabricated, two-rivet joint such as that shown in Fig. 1(*a*) may be considered in four stages: In the first stage static friction prevents slip; in the second stage the load is greater than the static friction, and the joint slips until the rivets come into bearing; in the

third stage, rivets and plates deform elastically so that the load-slip relation is linear; and, in the fourth stage, yielding of plates, rivets, or both, occurs until either plate fracture or complete shearing of the rivets results. This behavior is indicated by the diagrams of Fig. 1(*b*), which are reproduced from typical results of pilot tests on two-rivet joints tested at the University of Illinois[8] in connection with this investigation. The range of load over which Stage I extends is affected by the amount of friction between the plates. The friction depends on the tension in the rivets and the characteristics of the faying surfaces.

In Stage II, as slip progresses, the tilting of the rivets increases the pressure between the plates and hence increases the frictional resistance to movement. In lap joints, the bending due to eccentricity tends to cause the plates to peel apart at the ends and affects the amount of friction. These actions, together with the effect of non-uniform clearance around rivets, bending of the rivets, and distortion where contact is made between plates and rivets, extend Stage II over a range of load and cause the load-slip relation to take various forms.

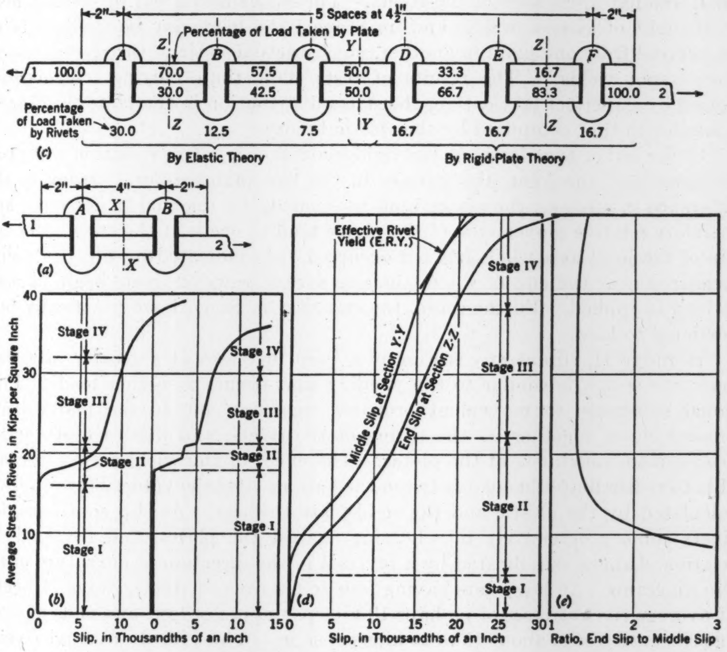

Fig. 1.—Action of Riveted Joints

Fig. 1(*c*) is a diagram of a joint with six rivets in line, showing the proportion of load transmitted by the rivets and the partition of load between plates, computed by the "elastic theory,"[9] which is based on the assumption that the rivets and plates deform elastically. Plate stresses in Fig. 1(*c*) are also computed on the assumption of equal load partition among rivets, which may be called the "rigid plate" theory. It is seen that by the elastic theory the end rivets take a relatively high percentage of load.

[9] "Work of Rivets in Riveted Joints," by A. Hrennikoff, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 99 (1934), pp. 437–489.

In Stage I, load is transferred from one plate to the other by friction. Stage I ends when the load is sufficient to cause movement of the joint as a whole—that is, when slip begins at the middle of the joint. This is shown by Fig. 1(*d*) in which the load-slip diagrams are generalized from the results of several tests in this investigation.

Although it is conceivable that the plates are in close contact over their entire faying surfaces, it seems likely that, in actual joints, owing to quilting action, the plates develop effective frictional resistance only over relatively small annular areas around the rivets. These localized areas of contact may be thought of as spot welds; and, in Stage I the load may be thought of as transferred from one plate to another, not by actual shear in the rivets, but by these "spot welds." The results of tests show that, barring irregularities caused by imperfect fabrication, the stress distribution in the plates in Stage I is similar to that computed by the elastic theory.

Under either the elastic or the rigid-plate theory, at any section except at the middle of the joint, the stresses in the two plates differ. Owing to the difference in stresses, the plates tend to elongate by unequal increments, and therefore relative movements of the plates tend to occur at the ends, although slip of the joint as a whole has not occurred. As indicated by Fig. 1(*d*), slips measured near the end of a joint having several rows of rivets begin as soon as load is applied. Furthermore, the end slips in Stage I are practically proportional to load.

In Stage II, slip at any section of a joint increases at a greater rate than load; the action is similar to the yielding that occurs at higher loads. Frictional resistance to movement probably increases due to the plates being pressed closer together by the tilting of the rivets, and due to tooth action arising from roughness of the plates. The effect of this yield action in Stage II is to redistribute the load between the various rivets to values between those calculated by the elastic and the rigid-plate theories. As slip continues, the rivets come progressively into bearing against the plates, and the load-slip relation changes as indicated by a reversal in the direction of curvature of the slip diagrams. In lap joints having four to six rows of rivets, Stage II begins at average rivet stresses of perhaps 10 kips per sq in., or less, and ends at average rivet stresses of about 15 to 25 kips per sq in. Thus, for the average riveted joint, the working range lies largely within Stage II.

In Stage III, where elastic action takes place with all rivets in full bearing, the ratio of end slip to middle slip is constant, as shown in Fig. 1(*e*), and remains so until plastic action begins. In this stage, the transfer of load at rivets again tends toward that called for by the elastic theory.

In Stage IV, yield occurs in the plates, rivets, or both; and slip again increases more rapidly than load. At the beginning, this increase in rate is caused in over-riveted joints by yielding of the plate material, and in under-riveted joints by yielding of the rivets; in either case there is no well-defined proportional limit. For other materials or structural members which may not have a well-defined yield, often a "useful limit point" (U.L.P.) is taken as that point on the stress-strain curve at which the rate of deformation is twice that below the proportional limit. Similarly, for the under-riveted joints of this investigation a load called the "effective rivet yield" (E.R.Y.) was taken as that where the rate of slip with respect to load was twice that in Stage III. In a balanced joint, there would be uncertainty as to whether the useful limit point or the effective rivet yield is reached first.

In the latter part of the yield range, rivets in the end rows of a number of the joints tested in this investigation sheared before the maximum load had been reached. The rivets in these joints were $\frac{7}{8}$ in. in diameter. Measurements of slip between plates at sections through the rivets indicated that premature rivet failure occurred when the detrusion was about 0.3 in.

It seems logical to suppose that in Stage IV, while the steels are deforming plastically, the partition of load among rivets tends to become equalized. The premature rivet failures caused by excessive strain cannot necessarily be interpreted as indicative of higher-than-average stresses in rivets near the ends of a joint.

DESCRIPTION OF SPECIMENS

There were forty pairs of joints, which are herein considered in three principal groups, as shown in Table 1. The specimens are identified by a series of letters and numbers. The first letter indicates the test series; the second is the initial of the plate steel (carbon, silicon, or nickel); and, the third is the initial of the rivet steel (carbon or manganese). For example, ASC denotes those specimens of Series A which have silicon-steel plates and carbon-steel rivets. The details of the specimens are shown in Figs. 2, 3, and 4.

TABLE 1.—CLASSIFICATION OF TEST SPECIMENS

Series	Number of pairs	Figure number	Kind of splice	Number of plates	Designed to fail in:	Variables
C, D	16	2	Lap	1	Plate	Net width; end pitch; plate thickness.
A	15	2, 3, and 4	Lap	1, 2, and 3	Rivets	Size of joint; rivet steel; plate steel.
B	3	2	Lap	1	Rivets	Pitch.
F	6	4	Butt, shingle	1, 2, and 3	Plates	Size of joint; butt *vs.* shingle splices.

In order not to unbalance the design of the joints more than necessary, when failure in the plates was desired the maximum expected strength of the plates was made equal to the minimum expected strength of the rivets. Conversely, when failure in the rivets was desired the maximum expected strength of the rivets was made equal to the minimum expected strength of the plates. The range in expected unit strengths, established from pilot tests at the University of Illinois,[8] is shown in Table 2. Table 2 also shows the working stress assigned to the various steels. Unless otherwise stated, the working load of a joint is taken as that which produces the working stress at the net section of the plates, even for joints designed to fail in the rivets. specimens, the net section was taken through the end row of rivets. In computing the area of net section, the diameter of the rivet hole was taken as the nominal diameter of the rivet, plus $\frac{1}{8}$ in. In computations involving rivet shear areas, the nominal diameter of the rivet was employed.

TABLE 2.—Range in Expected Unit Strength, and Working Stress

Steel	Unit Stress, in Kips per Square Inch

Manganese	....	....	....	71	92	20

Materials.—The steels were rolled at the Homestead plant of the Carnegie-Illinois Steel Corporation to the specifications of the San Francisco-Oakland Bay Bridge, which were similar to the corresponding specifications of the American Society for Testing Materials. All of the materials for the specimens met the specification requirements. The chemical properties of the steels were as listed in Table 3. The yield strength and ultimate strength of the mill coupons taken from plates are given subsequently in the tables showing the results of tests on joints (Tables 5, 9, and 17).

TABLE 3.—Chemical Properties of Steel
(Percentages of Total)

Copper	0.22	0.25 to 0.27	0.24 to 0.30	0.26	0.30

The physical properties of the rivet steel are shown in Table 4. The specimens were fabricated at the Ambridge plant of the American Bridge Company in accordance with the best commercial practice. For the carbon-steel and the silicon-steel plates, the rivet holes were sub-punched with a die of diameter $\frac{1}{8}$ in. less than the nominal diameter of the rivet, and the rivet holes were reamed to a diameter $\frac{1}{16}$ in. larger than that of the rivet. For the nickel-steel plates, the solid plates were assembled and the rivet holes were drilled to a diameter $\frac{1}{16}$ in. larger than that of the rivet. Rivets were driven with a hydraulic machine.

The temperature of carbon-steel rivets at the start of driving ranged from 1 400° F to 1 800° F with an average of 1 570° F. For manganese-steel rivets the range was 1 400° F to 1 900° F and the average 1 680° F.

* Tested at the mill. † Tested at the University of Illinois.

METHODS OF TESTING; INTERPRETATION OF DATA

Before each specimen was tested, gage lines for strain-gage observations were established at selected locations on the faces and edges of the plates; dials to determine the slip between adjacent plates were placed at one or more points along each edge; reference lines were scribed across each edge at intervals throughout the length; and, a coat of white brittle paint was applied to the faces of the plates.

The specimens were tested in the Southwark-Emery hydraulic testing machine at the University of California. Before the lower end of the specimen was gripped in the testing machine, initial strain-gage observations were taken. Up to a stress greater than the working stress but less than the yield stress, the load was applied in four or five increments, at a slow rate (approximately 500 lb per sq in. of gross section per minute). During the application of these load increments, observations of slip were made by means of the dial gages. After each increment of load had been applied, the load was maintained constant while strain-gage observations were made.

Above the highest load at which strains were measured, the load was applied at a faster rate, usually about 2 500 lb per sq in. of gross section per minute, up to the maximum load. During this final period of loading, the extent of plate scaling was recorded at intervals by means of photographs; written record was made of the progress of paint chipping from the rivet heads and of local failure of individual rivets or plate material; and, for some specimens the slip was observed by means of the dial gages up to about two-thirds of the estimated maximum load.

Determination of Yield Strength.—As load was applied, any marked yield or sudden slip in a specimen or its connections was reflected by a halt or lag in movement of the load-indicating gages of the hydraulic testing machine. For forty-two of the specimens, a semi-autographic record of the relation between load and time was obtained; for the other specimens, this relation was plotted from the log of the tests. On the load-time diagrams the successive loads at which various parts of the plates scaled were also noted. The yield load of the joint was taken as the first load at which the combined evidence of load lags and plate scaling was sufficiently marked so that it represented clearly the general behavior of the joint rather than minor sudden slips in the joint or in the pulling heads. Many of the joints did not exhibit a well-defined yield, and for seven of the joints no yield load could be assigned (Table 9, Specimens ASC54-2, ASM24-2, ASM36-2, ANM12-1, ANM24-2, ANM36-2, and BCC-20b-1). The yield loads determined as just described were probably close to those which might be determined from the load-elongation relations for the joint as a whole.

Attention is directed to the fact that herein the term "yield" does not indicate the same property as that reported for small joints by some investigators who considered yield as the load at which marked or sudden slip between plates first occurred.

Many of the joints with carbon-steel plates exhibited local scaling at loads appreciably below the yield load.

Usually, scaling of the plate began near rivets in the end row; and, for some specimens, the scaling through the yield range occurred largely outside the joint. It appears, therefore, that the yield strength, as determined, is a function of the stress conditions in the plate.

Determination of Effective Rivet Yield.—For joints failing in the rivets, it is believed that the load at which general rivet yielding occurs is of greater significance than the yield load based on plate action as just described. Herein a load called the "effective rivet yield" was determined, from the load-slip diagrams, as the point where the rate of slip with respect to load became twice the constant value it had attained while the joint was behaving elastically (Stage III, Fig. 1(*d*)). For the determination of this load, the slip measured at the middle of the joint was used; values obtained from slip measured at the ends of the joints were practically the same as those obtained from the middle slip. This load is analogous to the "useful limit point" used to define the practical proportional limit in materials or structural members which may not have a definite yield point. It was determined for all of the joints which had an effective rivet yield within the range of the slip measurements.

Use of Bending Frame.—The first three tests on lap joints disclosed that even at low loads the strains due to bending exceeded those due to direct stress, and that within the range of working loads the yield point of the steel was exceeded at critical locations. To reduce the bending within the length of the splice, the "bending frame" shown in Fig. 5 was used on most of the remaining lap joints (see Tables 5 and 9). After each increment of load had been applied to a specimen, the frame was adjusted until the bending within the length of the splice was reasonably small, as indicated by observations with a "curvemeter." The frame was removed after the last series of strain-gage observations had been completed.

Although the bending frame served its general purpose satisfactorily, the joints, as fabricated, were slightly warped and buckled both longitudinally and transversely, with the result that considerable local differences in bending stress were induced by loading and by application of the frame.

Determination of Curvature.—The curvometer used to determine curvature of the plate consisted of a rigid bar having at each end a leg which was applied to a gage point on the plate. At the center of the bar, a dial gage was mounted so that its plunger was in contact with the plate midway between the gage points. In order to convert the observed deflections into terms of bending strain at the surface of the plate, it was assumed that the elastic curve of the bent plate was a circular arc and that the neutral surface of the plate was midway between its faces.

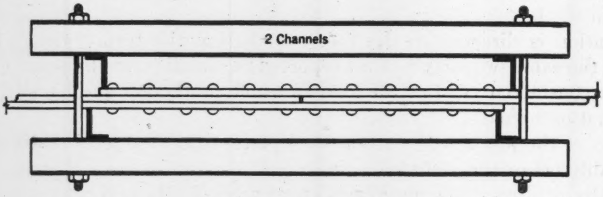

Fig. 5.—Bending Frame

Strain-Gage Measurements.—For most of the observations, 2.5-in., fulcrum-plate, strain gages were used; but for certain observations a gage length of 5, 10, or 20 in. was used. For a gage length of 2.5 in. the strain corresponding to the least reading by estimation was equivalent to a stress in the steel of 120 lb per sq in.

Many of the lap joints were curved while under load, even when the bending frame was used. The amount of bending within the length of the 2.5-in. strain-gage lines on the faces of the plates was determined, and curvature corrections were applied to the strain-gage observations.

With respect to the length of the joint, the longitudinal strain-gage lines were generally: (1) In the gross section of the plate outside of the splice; (2) in each space between rivet rows; and (3) spanning the rivet rows. Between rivet rows, for the single-plate and double-plate lap joints, in general, the gage lines were closely spaced on one-half of one face, and skeletonized on the remaining half of that face and on the opposite face. Corresponding gage lines were established on each edge of each plate. For the triple-plate lap joints and the butt joints, the observations were confined almost entirely to the edges of the plates. Transverse strains were measured only on the solid plates of Series C and D.

Slip Measurements.—The "slip," or relative movement of adjacent plates at a given section, was determined by means of dial gages, at the edges of the plates, by means of which movements of 0.0001 in. could be measured. Each gage on one plate was actuated by a lug attached to an adjacent plate. For very short, single-plate lap joints, the slip was measured at the middle of length; for the other single-plate lap joints, the slip at the ends was measured also. For multiple-plate joints, as a rule, the slip was measured at points where it was considered that minimum and maximum movement would occur in each single lap which composed a section of the joint as a whole. The slip gages were fastened to the plates at the middle of their thickness.

In many cases, sudden slips occurred during the progress of load application. In the majority of instances, after sudden slip occurred, the rate lagged temporarily, so that after an additional few thousand pounds had been applied the load-slip relation became coincident with what it would have been had the sudden slip not occurred. In these cases, the over-all characteristics were not altered by these erratic movements, and continuous curves are presented herein to show the general load-slip relation.

Although the middle slip is perhaps a characteristic of a joint acting as a whole, the end slip is considered significant with regard to the work done on the rivets in the end row. It is obvious that the distance of the end slip gage from the middle of the joint affects the ratio of end slip to middle slip. In making comparisons between joints, any differences in this distance should be taken into account.

Determination of Unit Elongation.—The elongation of a riveted joint under load includes both the strain in the plates and the slip between the plates. For use in determining the elongation, generally, a continuous chain of 2.5-in. and 10-in. strain-gage lines extended along each edge of the specimen. Furthermore, for some of the longer joints the over-all change in length was measured with an attached extensometer. For computing the unit elongation, the length of the joint was taken as the distance between ends of the plates forming the splice. The ratio of unit elongation of the joint as a whole to the unit elongation of the gross section of the plate, at the working load of the joint, is herein called the "elongation ratio." Although the unit elongation includes plastic deformation and slip as well as elastic deformation, it may be used as a basis for computing an effective modulus of elasticity of the joint.

The modulus of elasticity of the plates used in the joints was based upon strains measured on the plates outside the splice. The modulus generally ranged from 28 to 31 million lb per sq in.; the average was 29.7 million lb per sq in.

Computation of Joint Efficiency.—The efficiency was taken as the ratio of the stress in the gross section at ultimate load to the tensile strength of corresponding mill coupons. In this investigation, the efficiency was computed only for the specimens that failed in the plates.

Computation of Rivet Strength Ratio.—In so far as the performance of the rivet materials is concerned, a factor herein called the "rivet strength ratio" is of more significance than joint efficiency based on the plates which, for joints failing in the rivets, merely reflects the conditions of a particular design. The rivet strength ratio evaluates the performance of the rivets in a joint with respect to their potential shearing strength, as follows:

$$\text{Rivet strength ratio} = \frac{\text{Average shearing resistance per rivet in a joint}}{\text{Shearing strength of non-driven rivets in double shear}} \quad \cdots\cdots (1)$$

The ratio was computed only for the specimens that failed in the rivets.

‡ Ratio of unit elongation of joint to unit elongation of plate (gross section). § Failure in rivets.

‖ Ratio of stress in gross section of plate to corresponding strength of mill coupons.

TESTS OF LAP JOINTS DESIGNED TO FAIL IN PLATES; SERIES C AND D

The principal purpose of these tests on lap joints was to provide information regarding the efficiency of riveted tension members as influenced by: (1) The end pitch, or distance between the first and second transverse rows of rivets; (2) the effective net width of plate as controlled by the number of holes at a given section; and (3) the bearing stresses as controlled by thickness of plate.

The details of the specimens are shown in Fig. 2. All plates and rivets were of carbon steel. The rivets were 1 in. in diameter. The plates were nominally 21 in. wide, and were $\frac{3}{8}$ in. thick for Series C and $\frac{5}{8}$ in. thick for Series D. The $\frac{3}{8}$-in. material was thinner than required by standard specifications to develop the single-shear value of the rivets. Solid plates were included to provide data on the strength and efficiency (based on the strength of coupons) of wide plates without holes. The results of the tests are summarized in Table 5.

Tests of Solid Plates.—The efficiency at ultimate load, based on the strength of coupons tested at the mill, was 92% for the $\frac{3}{8}$-in. solid plates and 94% for the $\frac{5}{8}$-in. plates (Table 5). At the yield load, the efficiencies were 86% and 91%, respectively. These results are in agreement with those of other investigators.[7]

For loads up to 30 kips per sq in., longitudinal strains were the same at the middle of the plate as at the edge. For one $\frac{3}{8}$-in. specimen, the strains were measured at a stress of 35 kips per sq in., at which load the longitudinal strain was 11% greater at the middle of the plate than at the edge.

The specimens exhibited a marked yield at an average stress of 37.9 kips per sq in. for the $\frac{3}{8}$-in. plates and 34.8 kips per sq in. for the $\frac{5}{8}$-in. plates. The brittle paint on the specimens began to flake at stresses at, or slightly below, the yield point. This flaking exhibited the characteristic Lueders lines which started at the middle of the plate and progressed toward the edges as the loading was increased.

The plates failed by tearing apart at mid-length. For three specimens, a short transverse crack started at the middle of width of the plate; for the fourth specimen, the first crack started at one edge. The tendency for failure to start in the middle is attributed to the unequal distribution of longitudinal strain. The average elongation of the plates at failure was 29% in a 20-in. length. The reduction of area at failure was 28% for one $\frac{3}{8}$-in. plate and 35% for one $\frac{5}{8}$-in. plate.

Lateral and longitudinal strain-gage measurements were made on a grid of sixteen 5-in. squares which had been established on one $\frac{3}{8}$-in., and one $\frac{5}{8}$-in. solid plate. Within the working range, Poisson's ratio was found to be 0.28 for plates of both thicknesses. After failure, the ratio of lateral to longitudinal set was found to be 0.38 for the $\frac{3}{8}$-in. plate and 0.40 for the $\frac{5}{8}$-in. plate. These values are of interest in connection with the large transverse component of shear induced in widely spaced rivets in the end rows of long joints.

Effect of Number of Holes at a Given Section.—The effect of the number of rivets in the end row is shown in detail in Table 5 and summarized in Table 6. Of the riveted specimens, the highest total strength and efficiency was attained by the joints having five rivets in the end row at a gage distance of about 4 in. In the specimens having seven rivets in the end row at a gage distance of about 3 in., failure took place in the rivets rather than in the plates, although it is believed that plate failure was imminent at the time the joints ruptured.

For either of the sets of riveted joints, the calculated average stress in the net section at ultimate load was greater than that for the solid plates, as shown in Table 6. This difference is attributed in part to the difference between the assumed ($1\frac{1}{8}$ in.) and the actual ($1\frac{1}{16}$ in.) diameter of the rivet holes, and in part to what has been termed "the grooving effect" of notched plates.[10, 11] The joints having the lower bearing stresses ($\frac{5}{8}$-in. plates) exhibited the higher efficiencies.

TABLE 6.—EFFECT OF NUMBER OF RIVETS IN END ROW; SERIES C AND D

Plate thickness, in inches	NUMBER OF RIVETS		Symbol	Gage, in inches	Location of failure	Ratio of net to gross area	STRESS IN NET SECTION AT ULTIMATE LOAD		Efficiency percentages
	In first row	Total					Kips per square inch	Percentage of strength of solid plates	
3/8	0	0	CCC 0	....	Plate	1.00	62.5	100	91.5
	5	10	CCC 5	4	Plate	0.73	70.9	113	76.5
	7	8	CCC 7	$2\frac{7}{8}$	Rivets	0.61	74.9*	120*	67.5*
5/8	0	0	DCC 0	....	Plate	1.00	63.9	100	93.8
	5	16	DCC 5	$3\frac{1}{4}$	Plate	0.73	71.4	112	76.6
	7	14	DCC 7	3	Rivets	0.63	76.2*	119*	70.2*

* Strength of plates was higher than value shown, since failure was in rivets.

Effect of End Pitch.—The detailed test results for the group of joints to determine the effect of end pitch on strength and efficiency are shown in Table 5. All specimens failed in the plates along lines that passed through the rivet holes of the end row, as illustrated in Fig. 6. For the shorter end pitches, the fractures generally followed a zigzag course, passing through rivet holes in the first and second rows. The tendency for the fractures to extend through both end rows of rivets was less for the $\frac{3}{8}$-in. plates than for the $\frac{5}{8}$-in. plates, possibly because of higher bearing stresses in the $\frac{3}{8}$-in. plates. Furthermore, the $\frac{3}{8}$-in. plates exhibited a pronounced bulge at the end, opposite each end rivet, and the extent of this bulging was greater than that in any of the other specimens tested.

Fig. 7 shows a typical joint, with $\frac{5}{8}$-in. plates, after failure. The reduction in percentage of paint scaling from top to bottom of the splice reflects the transfer of stress from the near, to the far, plate. The characteristic Lueders lines where the mill scale and white paint have flaked off show the direction of maximum shear in the plate between rivets. The scaled areas at the front (upper) edges of the rivet heads indicate that the rivets have tilted forward as load was applied. At the bottom of the splice, it is seen that the slip between adjacent plates was about $\frac{3}{8}$ in. It is of interest to note also the extent to which the highly stressed section of the lower plate contracted laterally.

[10] "Johnson's Materials of Construction," by M. O. Withey and James Aston, John Wiley & Sons, Inc., New York, N. Y., Edition 7 (1930), pp. 663–666.

[11] "Strength of Materials," Part II, by S. Timoshenko, D. Van Nostrand Company, New York, N. Y., 1930, pp. 673–674.

The efficiencies of the joints at ultimate load, shown in Table 5, Column (20), are summarized in Table 7. The maximum difference in strength of joints with a given plate thickness was only about 5 per cent. Within this range, the $\frac{3}{8}$-in. specimens having staggered end rivets with an end pitch of 2 to 6 in. were less efficient than those with zero end pitch (five rivets in the end row). The $\frac{5}{8}$-in. specimens with staggered end rivets were somewhat more efficient than those with zero end pitch. If plates thicker than $\frac{5}{8}$ in. had been used, it is possible that the relative strength of the joints with staggered rivets would have been somewhat higher.

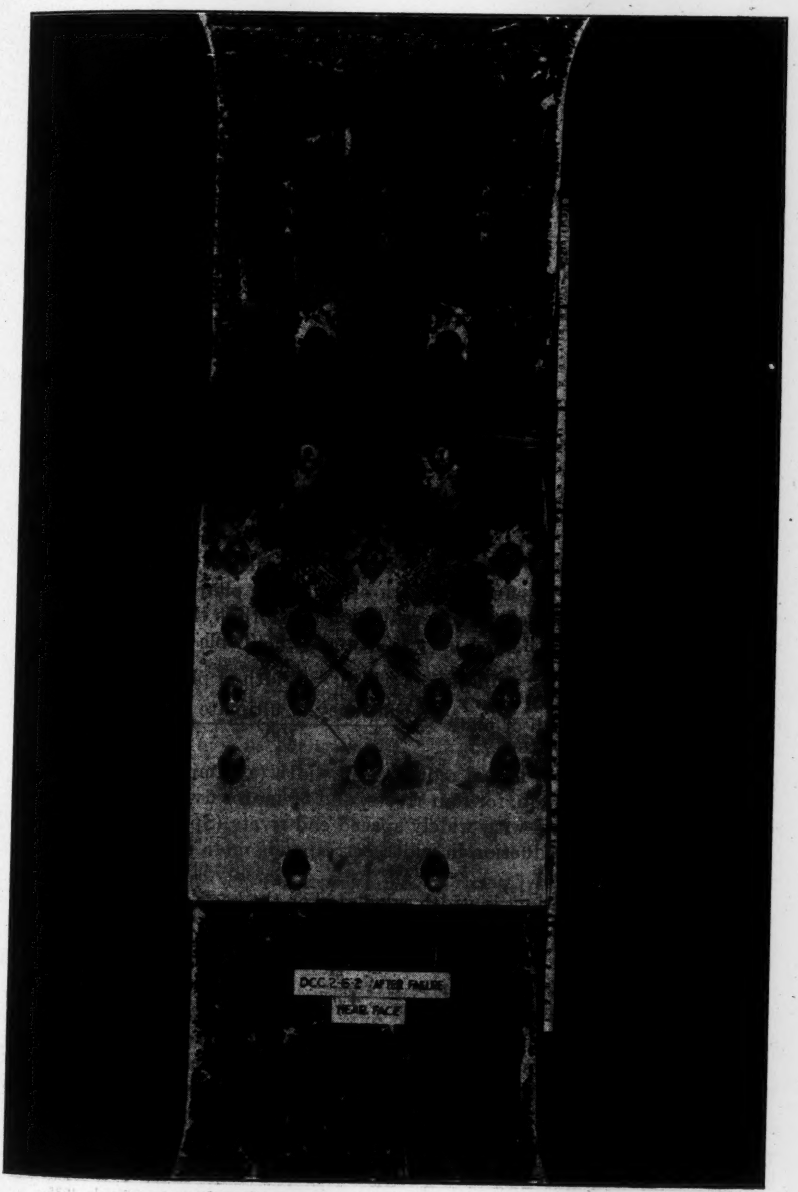
FIG. 6.—LOCATION OF FRACTURE; SERIES C AND D; VARIABLE END PITCH

For both thicknesses of plate there was a decrease in the efficiency of the joints when the end pitch exceeded 4 in. A possible explanation is that the



DCC 2-6-2 AFTER FAILURE
REAR FACE

FIG. 7.—TYPICAL PLATE FAILURE; SERIES D

high concentrations of stress at the extreme rivets of the longer joints precipitated plate failure. The efficiency of specimens in Series C ($\frac{3}{8}$-in. plates) was less than that for specimens in Series D ($\frac{5}{8}$-in. plates), possibly because of the higher bearing stresses in the $\frac{3}{8}$-in. specimens.

TABLE 7.—EFFECT OF END PITCH; SERIES C AND D

Series	Plate thickness, in inches	NUMBER OF RIVETS		PERCENTAGE EFFICIENCY OF JOINT, FOR THE FOLLOWING END PITCH					
		End pitch, 6 inches to 2 inches	End pitch, 0 inches*	End pitch, 6 inches	End pitch, 5 inches	End pitch, 4 inches	End pitch, 3 inches	End pitch, 2 inches	End pitch, 0 inches
CCC	3/8	12	10	74.9	74.4	75.0	73.4	72.8	76.5
DCC	5/8	20	16	77.7	78.1	78.8	78.6	....	76.6

* Five rivets in end row; other joints have two rivets in end row and three rivets in second row.

Effective Net Section.—The results of a study to determine the effective reduction in width of plates due to rivet holes are shown in Table 5, Column (21). The calculation is based on the assumption that the potential strength of a joint is the product of the strength of the mill coupons and the gross cross-sectional area of the plate; this assumption is not strictly true, as shown by the fact that the efficiency of the solid plates CCC0 and DCC0 was only 92% and 94% respectively. The effective width of a riveted plate is the gross width times the efficiency. The effective reduction in width is then the gross width minus the effective width; that is (see Column (21), Table 5)

$$\text{Effective reduction in width} = \text{Width of plate}$$
$$- \left(\text{Width of plate} \times \frac{\text{Efficiency at ultimate load}}{100} \right) \ldots\ldots\ldots (2)$$

Corresponding values of actual reduction in width (assuming $1\frac{1}{8}$-in. holes) are $2\frac{1}{4}$ in. for two rivets, $4\frac{1}{2}$ in. for four rivets, and $5\frac{5}{8}$ in. for five rivets. It is seen that for all of the joints with widely spaced end rivets (Specimens CCC2 and DCC2) the effective reduction in width corresponds more nearly to five rivets than to two rivets.

The effective reductions in width calculated on the basis of a typical formula used in current specifications[12] are shown in Column (22), Table 5. The formula is:

$$x = 1 - \frac{s^2}{4\,g\,h} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

in which x = the fraction of the hole to be deducted from b; s = the pitch, or the stagger; g = the gage of any two successive holes in a chain; and h = rivet diameter plus $\frac{1}{8}$ in. It is apparent that these requirements bear no relation to the results of the tests.

These results show that the use of fewer rivets in the end rows than in the interior rows does not make for the efficiencies that are calculated in accordance with common practice. The yield strengths (Table 5, Column (15)) show no large or consistent effect of end pitch or number of rivet holes at a given section on yield of joint.

[12] "Standard Specifications for Highway Bridges," Am. Assoc. of State Highway Officials, 1935.

TESTS OF LAP JOINTS FAILING IN RIVETS; SERIES A AND B

As shown in Figs. 2, 3, and 4, the specimens of Series A consisted of fifteen pairs, which included three different lengths of lap joint for five different combinations of rivet and plate material, as listed in Table 8. The joints were designed to fail in the rivets, and for a given length were designed to be of approximately equal strength. Lap, rather than butt, joints were used since within the capacity of the testing machine a greater variation in length of joint could be obtained by designing the specimens for single rather than double shear in the rivets. Lap joints also permitted the location of strain gages across the face of the main plates. The arrangement of the lap joints resulted in an eccentricity of $\frac{5}{8}$ in. for all joints. The uncertainties arising from, and the measures taken to correct for, the moments produced by this eccentricity have been mentioned previously herein (see headings, "Methods of Testing; Interpretation of Data: Use of Bending Frame," "Determination of Curvature" and "Strain-Gage Measurements").

TABLE 8.—CHARACTERISTICS OF SPECIMENS; SERIES A

Length of joint, in inches	PLATES (ALL $\frac{5}{8}$ INCH)			NUMBER OF RIVETS (ALL 1 INCH)	
	No.	Width in inches	Steel	Carbon steel	Manganese steel
20 to 29	1	26 20.5 18	Carbon Silicon Nickel	18 18	12 12 12
39 to 57	2	26 20.5 18	Carbon Silicon Nickel	36 36	24 24 24
58 to 85	3	26 20.5 18	Carbon Silicon Nickel	54 54	36 36 36

The specimens of Series A were designed to furnish the following information:

(1) Effect of length of joint upon average shearing resistance of rivets;
(2) Effect of plate material upon average shearing resistance of rivets;
(3) Comparative behavior of carbon-steel and manganese-steel rivets;
(4) Partition of rivet shear among the several transverse rows of rivets;
(5) Relation between the average shearing resistance of rivets and the shearing strength of non-driven rivets; and,
(6) Desirable ratio of tensile stress in plates to shearing stress in rivets, for use in design of large riveted connections.

The specimens of Series B consisted of three pairs of lap joints with $\frac{3}{4}$-in. by 28-in. carbon-steel plates and twenty-two 1-in. carbon-steel rivets arranged in full rows of four rivets (Fig. 2). The rivet pitch throughout the joint was

‖ No yield load indicated by load rate data.

¶ Ratio of average rivet strength in the joint to strength of undriven rivets in double shear.

** One, two, or more rivets failed, as indicated by snaps in joint during loading; number could not be observed.

varied from 3 to 6 in., in order to determine the effect of pitch on strength of joint.

The results of tests on Series A and Series B are shown in Table 9. This table also gives the test results for two pairs of specimens of Series C and D (CCC7 and DCC7), which specimens failed in the rivets.

Series A

Strength.—The average strength of the rivets at ultimate load was obtained by dividing the total load by the total shearing area of rivets, based on the nominal diameter of the rivet. As between large and small joints of the same plate and rivet steel, the maximum difference in average rivet strength was only about 10%, as shown in Table 10, composed of selected data from Table 9.

TABLE 10.—RIVET STRENGTH OF LARGE AND SMALL JOINTS; SERIES A (Average Rivet Strength at Ultimate Load)

Plate steel	CARBON-STEEL RIVETS						MANGANESE-STEEL RIVETS					
	Kips per Square Inch			Percentages			Kips per Square Inch			Percentages		
	One plate	Two plates	Three plates	One plate	Two plates	Three plates	One plate	Two plates	Three plates	One plate	Two plates	Three plates
Carbon........	55.7	51.1	50.0	100	92	90	75.9	77.4	71.4	100	102	94
Silicon.........	54.8	54.0	51.1	100	99	93	72.4	78.0	72.7	100	108	100
Nickel.........	....	....	....	....	....	....	74.7	77.7	75.7	100	104	101

For the joints that had carbon-steel rivets in combination with a given plate material, the highest rivet strength was exhibited by the short (single-plate) joints and the lowest by the long (triple-plate) joints. However, for the joints that had manganese-steel rivets, the intermediate (double-plate) joints exhibited the highest rivet strength.

In order to investigate the reason for the somewhat higher strength of the manganese-steel rivets in the double-plate joints, two selected rivets from each of three joints were subjected to hardness tests. The rivets in the double-plate joint were found to be harder than those in the single-plate and triple-plate joints; furthermore, photomicrographs showed that the rivets in the double-plate joint had a finer grain structure. The difference may have been due to variations in cooling conditions. Another variable was the driving temperature, which averaged 100° F lower for the rivets of intermediate grip than for the other rivets.

The rivet strength ratio, or the ratio of the average shearing resistance per rivet in a joint to the shearing strength of non-driven rivets in double shear, is shown in Table 9, Column (28), and is summarized in Table 11.

The manganese-steel rivets exhibited higher rivet strength ratios than the carbon-steel rivets. As between the two kinds, the actual length of splice may have had some influence upon the rivet strength ratio; the joints with carbon-steel rivets contained two more rows of rivets per lap and were somewhat longer than the corresponding joints with manganese-steel rivets (see Figs. 2, 3, and 4; Series A). For these joints, all of which failed in the rivets, the kind of plate steel appeared to have no marked or consistent influence on the strength or the rivet strength ratio. As a group, the joints having manganese-steel rivets and nickel-steel plates exhibited the highest rivet strength ratios of any of the joints in the entire investigation.

TABLE 11.—Rivet Strength Ratios; Series A
(Percentages)

Plate Steel	Carbon-Steel Rivets			Manganese-Steel Rivets		
	One plate	Two plates	Three plates	One plate	Two plates	Three plates
Carbon	133	122	119	139	142	131
Silicon	130	129	121	133	143	134
Nickel	....	....	....	137	143	139

Effective Rivet Yield.—In an under-riveted joint the effective rivet yield has more significance, so far as rivet performance is concerned, than the yield strength of the joint. Average values of effective rivet yield, yield strength, and ultimate strength, taken from Table 9, are shown in Table 12. For a given rivet steel, the effective rivet yield did not vary greatly; and for both kinds of rivet steel, the effective rivet yield averaged 62% of the ultimate strength of rivets in the joints of this series (Series A). The yield strength of the joints varied with the type of plate steel as well as the type of rivet steel, so that the ratio of yield strength to ultimate strength was not constant.

TABLE 12.—Effective Rivet Yield, Yield Strength, and Ultimate Strength; Series A

Plate Steel	Carbon-Steel Rivets						Manganese-Steel Rivets					
	Rivet Stress, in Kips per Square Inch			Ratios of Rivet Shears			Rivet Stress, in Kips per Square Inch			Ratios of Rivet Shears		
	Effective rivet yield	Yield	Ultimate	$\frac{\text{Column (2)}}{\text{Column (3)}}$	$\frac{\text{Column (2)}}{\text{Column (4)}}$	$\frac{\text{Column (3)}}{\text{Column (4)}}$	Effective rivet yield	Yield	Ultimate	$\frac{\text{Column (8)}}{\text{Column (9)}}$	$\frac{\text{Column (8)}}{\text{Column (10)}}$	$\frac{\text{Column (9)}}{\text{Column (10)}}$
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)	(12)	(13)

Average	32.8	39.0	52.8	0.84	0.62	0.74	46.5	61.2	75.1	0.76	0.62	0.82

The ratio of effective rivet yield to the yield strength and ultimate strength in tension of rivet-rod stock did not differ greatly as between the two kinds of

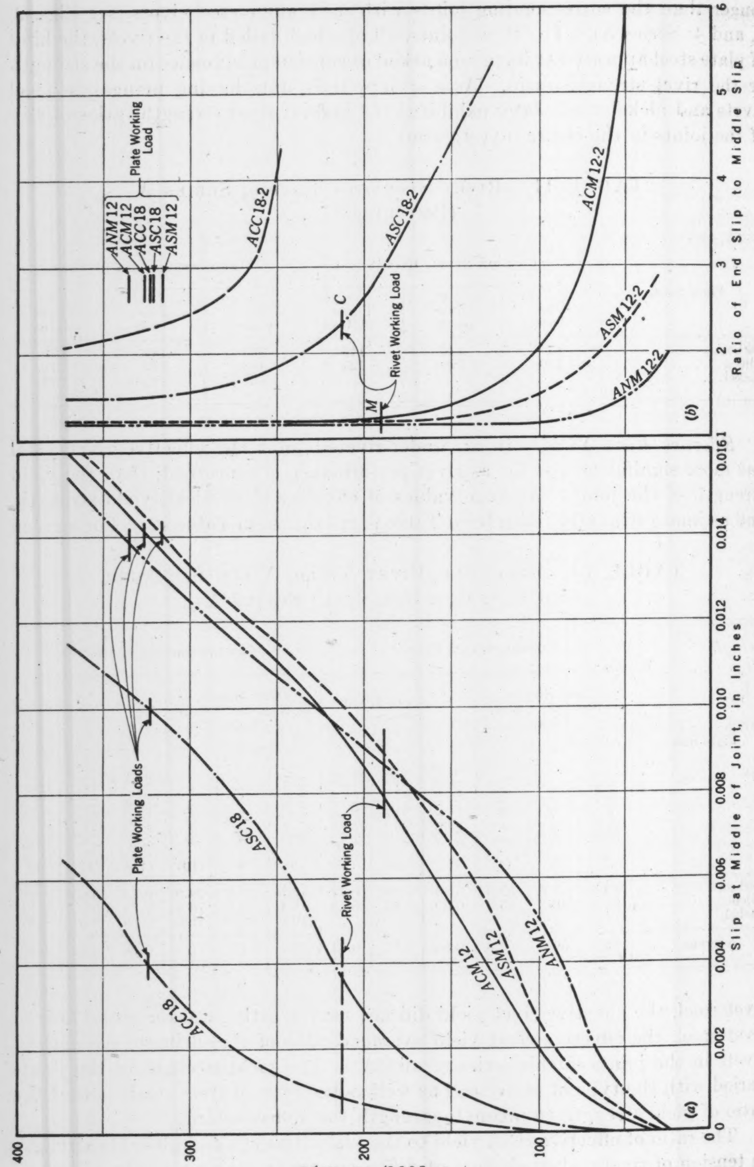

FIG. 8.—LOAD-SLIP RELATIONS FOR SINGLE-PLATE JOINTS OF SERIES A

rivet steel; for example:

Ratio	Carbon-steel rivets	Manganese-steel rivets
$\frac{\text{Effective rivet yield}}{\text{Yield strength in tension}}$	0.83	0.85
$\frac{\text{Effective rivet yield}}{\text{Tensile strength}}$	0.57	0.57

Slip.—The results of observations to determine slip for the joints of Series A are shown in Figs. 8 to 10. For the single-plate joints, Fig. 8(*a*) shows the

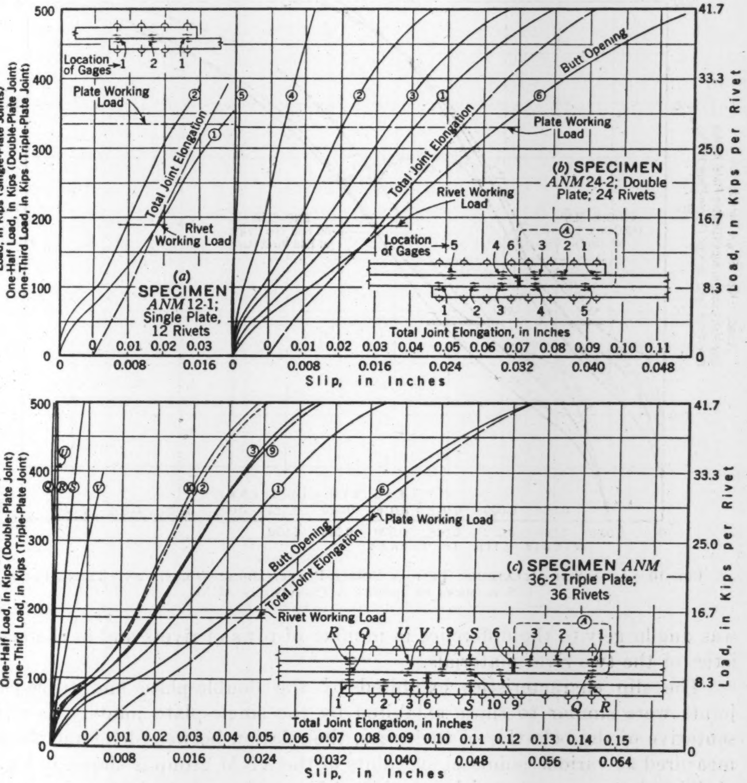

FIG. 9.—LOAD-SLIP RELATIONS AT VARIOUS PLACES ON TYPICAL SPECIMENS OF SERIES A

relation between load and middle slip. The joints with eighteen carbon-steel rivets (Specimens ACC18 and ASC18) slipped considerably less than those with twelve manganese-steel rivets, even if the slip were taken at the same load per rivet. Of the joints with carbon-steel rivets, those having carbon-steel plates slipped less than those having silicon-steel plates. All of the joints having manganese-steel rivets exhibited similar slip characteristics.

Fig. 8(*b*) shows the relation between load and the ratio of end slip to middle slip for one specimen of each of the pairs of single-plate joints. The end slip was measured midway between the first and second rows of rivets. Values in Fig. 8(*b*) are for one specimen of each pair. A constant ratio of end slip to middle slip—taken to be an indication that the rivets had come into full bearing—was attained at lower loads by the joints with twelve manganese-steel rivets than by those with eighteen carbon-steel rivets. Probably the difference was due largely to the difference in number of rows of rivets and in characteristics of the two rivet materials.

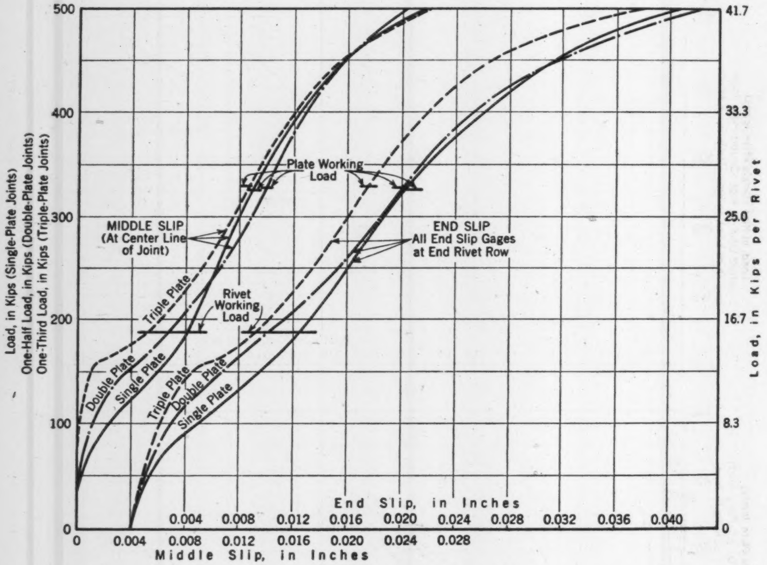

FIG. 10.—LOAD-SLIP RELATIONS; TYPICAL SINGLE-PLATE, DOUBLE-PLATE, AND TRIPLE-PLATE SPECIMENS OF SERIES A (SPECIMENS ACM)

The slip characteristics exhibited by the double-plate and triple-plate joints were similar to those exhibited by the single-plate joints. As representative of the behavior of the series, the relation between load and the slip measured at various points along joints of the ANM group is shown in Fig. 9. The plates were all of nickel steel, $\frac{5}{8}$ in. by 18 in.; and all rivets were of manganese steel, 1 in. in diameter. The relative movement of plates at the slip-gage locations is indicated by half-arrows in the inset diagrams. In the double-plate joint, the portion enclosed by the dotted line marked "A" (see inset, Fig. 9(*b*)) may be considered the equivalent of a single-plate lap joint, since at the end of the double-plate joint half of the total load is carried by each plate; and, at the middle of length of the joint, the load on the inner plate is zero while the outer plate still carries half the load. Similar characteristics hold for the triple-plate joint. Comparison of the end slips at Gage Locations 1 of the single-plate joint with those at Gages 1 and 3 of the double-plate joint, and at Gages 1, 3, and 9 of the triple-plate joint, shows that the slips at both ends of equivalent single laps in the multiple-plate joints did not differ greatly from the end slips for the single-plate joint at corresponding loads. Furthermore, in the multiple-plate joints, the "middle" slips (measured at all Gage Locations 2 and, for the triple-plate joint, at Gage 10 also) were similar to the middle slip of the single-plate joint. Slips at other points show the relative movements of the plates throughout the length of the joints.

A comparison of the relative magnitude of end and middle slip for a single, a double, and a triple-plate joint is afforded by the curves in Fig. 10. For the same unit stress in the plates, the middle slips and likewise the end slips were about the same as between the three sizes of joint. As in Fig. 8(*b*), the values are for one specimen of each pair.

The values of end slip at the rivet working load are summarized in Table 9, Column (16). With a few individual exceptions, the slips for single, double, or triple plates in any group having the same plate and rivet material were about the same. As noted in connection with the single-plate joints, the joints having carbon-steel rivets exhibited less slip than corresponding specimens having two-thirds as many manganese-steel rivets.

Four stages of action in riveted joints are indicated by the load-slip relations (see Fig. 1 and accompanying text). For the single-plate joints of Series A, Table 13 shows the approximate loads at the end of Stage I (no slip at middle of joint), at the beginning of Stage III (full bearing of all rivets, linear load-slip relation), and at the effective rivet yield which occurs when Stage IV is well started. For most of the joints, the rivet working load fell in Stage II; only for the specimens with manganese-steel rivets and nickel-steel plates was the working load definitely in Stage III.

Elongation.—The unit elongation of each joint relative to that of the main plate (gross section) varied from 1 to 2 at the plate working load (Table 9, Column (18)). The larger the joint, the less was the elongation ratio. It appears that the ratio was affected principally by the factors that influenced slip. For a single, a double, and a triple-plate specimen having nickel-steel plates and manganese-steel rivets, the variation in total elongation with increase in load is shown in Fig. 9.

Distribution of Strain.—The variation in longitudinal strain along a single, a double, and a triple-plate joint is illustrated in Fig. 11, for a stress at net section of 20 kips per sq inch. These curves (all edge strains) show that in the multiple-plate joints the stress in the outer plates was maintained at approximately the full value up to the beginning of the lap at the far end of the joint (marked "X"); between this point and the end of the plate the decrease in stress was similar to that in a single-plate lap joint. Irregularities in the strain diagrams may be due in part to localized stresses near the rivets and inequalities arising from fabrication.

Typical variations in longitudinal strain across a carbon-steel plate ($\frac{5}{8}$ in. by 26 in.) are shown in Fig. 12. The diagrams for Specimen ACC18-2 (eighteen, 1-in. carbon-steel rivets) show the observed strains, the corrections in strain determined by means of the curvometer, and the corrected strains, for a plate stress (at net section) of 20 kips per sq in. The diagrams for Specimen ACM12-2 (twelve, 1-in. manganese-steel rivets) show the corrected strains at plate stresses of 10 and 20 kips per sq in. The average strain across any section, employed in the load-partition studies discussed subsequently, was obtained by measuring, by planimeter, the areas under the corrected strain-distribution curves for each load.

Partition of Load Among Rivets.—The partition of load among rivets in the various transverse rows, determined from strain measurements along gage lines located between the rivet rows, is shown in Fig. 13. Data are shown for selected single-plate joints of each of the five types; for all of these specimens the bending frame (Fig. 5) was used to reduce the curvature of the plates, and curvemeter observations were made to provide a correction for change in curvature during loading. The curves show the percentage of the total load taken by a rivet in each row. Although there may be considerable error in the individual results, it is believed that the values are sufficiently accurate to show quantitatively the action of the joints tested. For this series, the specimen number defines the physical characteristics of each specimen; thus: ACM12-2 denotes Series A; Carbon-steel plates; Manganese-steel rivets; 12 rivets per joint; and the second specimen of the pair tested.

The load partition is shown at each of four loads, which differ as between the several types of joint. These loads varied from about one-half to about twice the rivet working loads. All the loads at which observations were taken lay above Stage I of joint action. Most of the observations were taken at loads within Stage II, which ended at rivet stresses of about 13 to 27 kips per sq in. For the joints with manganese-steel rivets, the third and fourth loads lay in Stage III; and for the joints in this group which had nickel-steel plates, the second load also lay in Stage III.

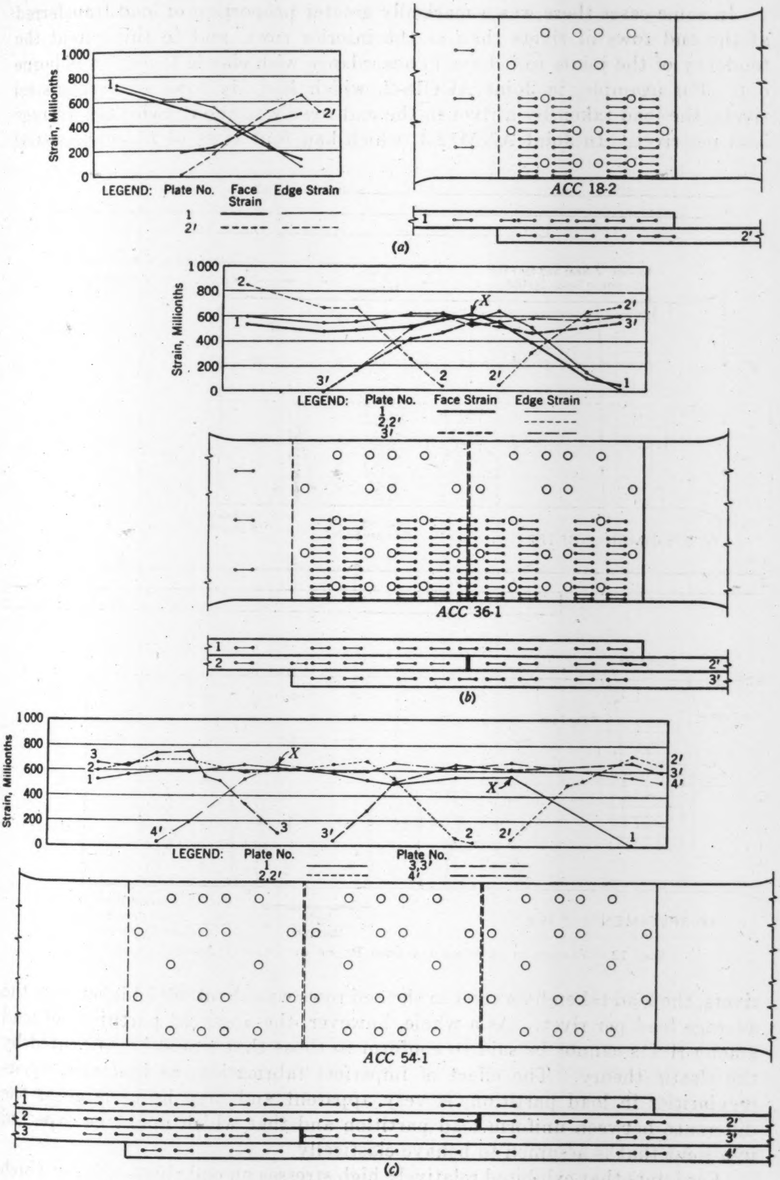

FIG. 11.—VARIATION IN STRAIN ALONG TYPICAL JOINTS OF SERIES A

In some cases there was a markedly greater proportion of load transferred at the end rows of rivets than at the interior rows, and to this extent the tendency of the joints to behave in accordance with elastic theory[9] was borne out. For example, in Joint ACC18-2, which had six rows of carbon-steel rivets, the load taken by a rivet in the end rows was about twice the average load per rivet. In Joint ANM12-1, which had four rows of manganese-steel rivets, the load taken by a rivet in the end rows was about 20% higher than the average load per rivet. As a whole, however, the observed partitions of load among rivets cannot be said to conform to those that would be computed by the elastic theory. The effect of imperfect fabrication, as indicated by irregularities in load partition, is very apparent and may be as large as the difference between uniform load partition and that which might be expected in a joint that is assumed to behave elastically.

FIG. 12.—VARIATION IN STRAIN ACROSS PLATE OF TYPICAL JOINTS; SERIES A

For joints that exhibited relatively high stresses on end rivets and for which two or more of the loads lay in Stage II (ACC18-2, for example) increasing the load reduced the share taken by the end rivets and tended toward more uniform partition of load. Upon this observation is based the preceding general statement that load partition is more nearly uniform in Stage II than in Stage I in which the joint may be behaving elastically (see text applying to Fig. 1).

For Specimen ANM12-1, in which the load partition tended to approach that required by elastic theory from the beginning, the relative stresses taken

by the end rivets increased for the last two loads which were definitely in Stage III. This would indicate that after Stage II is passed, the load partition is again built up so as to approach, but not necessarily to conform to, that indicated by the elastic theory.

The elastic theory is not considered to be suitable for the prediction of load partition among rivets of a joint because: (1) The partition of load tends to vary through the successive stages of joint action, (2) ideal joints are not produced commercially, and (3) considerable slip occurs within the working range so that—except for short joints with high-strength plate and rivet materials—the rivets do not come into full bearing until the joint is stressed above the working load.

Premature Rivet Failures.—The number of individual rivets failing before complete rupture of the joint is shown in Table 9, Column (29). In nearly all cases of premature rivet failure, the rivets were in the end row of a lap; in the remaining cases, the rivets were in the second row of a lap and failed only after rivets in the first row had failed. For three of the triple-plate joints premature failures occurred in the end row of rivets of an interior lap.

Of the single-plate joints of Series A, only one pair (ACC-18) exhibited premature rivet failure (Table 9, Column (29)). In the multiple-plate joints, the number of premature rivet failures was: (*a*) Greater for triple-plate joints than for double-plate joints; (*b*) greater for joints with carbon-steel rivets than for joints with two-thirds as many manganese-steel rivets; (*c*) greater for joints with carbon-steel plates than for joints with silicon-steel or nickel-steel plates; and (*d*) zero for the joints having nickel-steel plates in combination with manganese-steel rivets. It may be concluded that the strain imposed on the end rivets at loads approaching the ultimate for the joint is greater for the larger joints, greater for the longer (less compact) joints of a given nominal size, and greater for the more ductile steels.

The occurrence of premature rivet failures at the ends of a joint is not necessarily an indication that at loads approaching failure the end rivets carry greater than the average load per rivet. Although direct evidence is lacking, it seems likely that the load partition between rivets tends toward uniformity while the rivets are yielding. The fact that premature rivet failures did not occur with the less ductile steels indicates that excessive detrusion, rather than stress, caused such failures.

Series B

In the specimens of Series B (Fig. 2), the rivets were arranged in full rows of 4 each, at a gage distance of 7.5 in., which is wider than would ordinarily be used with full-row riveting. The approximate values of load at various stages of joint action are shown in Table 14. Compared with similar joints in Series A, the joints of Series B exhibited relatively low slip. For example, as shown by the values in Table 9, Column (16), the slip of the joints of Series B at the rivet working load was less than half that of Joints ACC18.

TABLE 14.—AVERAGE STRESS IN RIVETS AT VARIOUS STAGES OF JOINT ACTION; SERIES B

Specimens	Pitch, in inches	RIVET STRESS, KIPS PER SQUARE INCH		
		Working Load	End Stage I	Begin Stage III
BCC20*a*	3	15	10	25
BCC20*b*	4.5	15	9	23
BCC20*c*	6	15	7	21

The differences in strength for all the specimens of Series B were small, although the joints with a pitch of 4.5 in. (0.6 of gage distance) were somewhat stronger than either the shorter or the longer joints. If the gage distance had been smaller (say, four or five rivet diameters) the optimum ratio of pitch to gage would not necessarily have been the same as in these specimens. Test results are summarized in Table 15. Specimens ACC18 of Series A (see Fig. 2) were not greatly different from the specimens of Series B except with regard to rivet pattern; in specimens ACC18 the net section was supposedly protected by having only two rivets in the first row and three rivets in the second row. Table 15 shows that these joints were not quite as efficient as the joints of Series B which had the full number of rivets in the end row. The last column of Table 15 confirms the discussion of Series A to the effect that end rows of rivets are subjected to larger strains in long splices than in short splices.

TESTS OF BUTT AND SHINGLE JOINTS; SERIES F

For heavy tension members, the use of a "shingle" splice results in considerable economy of material and a shorter rivet grip than does the conventional butt splice. The specimens of Series F, shown in Fig. 4, were designed for comparison between butt and shingle splices. The plates were of silicon steel, 20 in. wide, and all main plates were $\frac{11}{16}$ in. thick. The rivets were of carbon steel and were $\frac{7}{8}$ in. in diameter. The distinguishing characteristics of the six pairs of specimens were as shown in Table 16. With the intention of insuring plate failure, the ratio of tensile stress in the plates to shearing stress in the rivets (T : S ratio) was made 1 : 0.54 (28 000 : 15 000) instead of the

TABLE 16.—TYPES OF SPECIMEN; SERIES F

1 : 0.57 (93 000 : 53 000) established for rivet failure as a result of the pilot tests. In spite of this provision, in all specimens, except the single-plate butt joints FSCA, one or more rivets failed before plate failure occurred. The results of the tests are shown in Table 17 and Figs. 14 to 18 inclusive.

Behavior of Individual Joints

In order to secure a more general picture of the behavior of the parts of these joints than that afforded by the slip measurements alone, a series of 2.5-in. strain-gage lines was located on the edges of the plates, for one specimen of each pair. In calculating the share of the load taken by the various plates at any given section from the edge strains, it was necessarily assumed that the load transferred across a section was proportional to the observed strain. It is believed that the error involved in this assumption was reasonably small in the case of the multiple-plate joints since these joints had full-row riveting over a large proportion of the length.

* Length of inner (long) splice plates.
† Ratio of average unit elongation of joint to unit elongation of plates (gross section).
‡ Ratio of stress in gross section of plate to corresponding strength of mill coupons.

The behavior under load and the manner of failure, which are of particular interest in the case of the multiple-plate joints, are shown in Figs. 14 to 17, inclusive. In the figures, Diagrams *A* and *B* are the edge and face views of a joint and show rivet locations, gage-line locations, and the lines along which the parts of the joint separated at failure. In general, the location of final failure is shown for one of the two specimens at the left end of the diagrams and for the other specimen at the right end. In Diagrams *B*, a cross or a heavy dot drawn at a rivet location indicates that the rivet failed before complete rupture of the joint. Diagrams *C* show the percentage of load taken by each plate; the values were obtained from strain data by taking the summation of strains in all plates at any transverse section as 100 per cent. The points in Diagrams *C* correspond to the centers of the gage lines in Diagrams *A*. The stepped lines show the load that would be taken by each plate, calculated on the assumption of equal partition of load among rivets.

§ P = plate; and R = rivet.

‖ Based on total number of rivets in joint.

¶ Excluding rivets which failed before maximum load was attained.

In all the specimens of this group of tests (Figs. 14 to 17) the main plates were $\frac{11}{16}$-in. by 20-in. silicon-steel plates, held by $\frac{7}{8}$-in. carbon-steel rivets (see Fig. 4). Slip gages were attached to both edges. In the single-plate and double-plate joints (Figs. 14 and 16(*a*)) the stress at the net section, 18.75 kips per sq in., was the average of 7.5, 15, 22.5 and 30 kips per sq in. In the triple-plate joints (Figs. 15, 16(*b*), and 17) the stress at the net section, 22.5 kips per sq in., was the average of 15 and 30 kips per sq in.

Single-Plate Butt Joints FSCA.—The strains in the main and splice plates were measured along chains of 2.5-in. gage lines, as shown in Fig. 14(*a*), Diagram *A*. The load partition computed from the strain is shown in Diagram *C*. Studies based on these data indicate that at the given loads the rivets in the end rows took more than the average share of the load, although the observed strains were undoubtedly affected by their location with respect to the various rivet rows which contained different numbers of rivets. The specimens failed entirely in the plates through an end row of rivets, as shown in Diagrams *A* and *B*, Fig. 14(*a*). First, the plate was torn from one end rivet to the edge, then the entire plate ruptured suddenly. The fracture was square and of a coarse, granular texture. Scaling of brittle paint from rivet heads occurred only in the end rows.

Double-Plate Butt Joints FSCB.—Strains were measured along chains of 2.5-in. gage lines on the edges of the plates, as shown in Fig. 14(*b*), Diagram *A*. Studies indicated that over the given range of loading the load per rivet was highest in the end row and in the two interior rows (9 and 10) next to the butt. In general, the progress of rivet scaling confirmed the load distribution determined from the strain measurements; marked scaling occurred in Rows 1, 10, 9, 8, and 7 in that order, whereas there was little scaling in Rows 2 and 3 and none in Rows 4, 5, and 6. At the end of the outer (short) splice plates, the inner (long) splice plates carried about 41% of the total load, as shown in Diagram *C*, Fig. 14(*b*). At the butt, the inner splice plates comprising 54% of the splice material carried about 58% of the total load, and the outer splice plates comprising 46% of the splice material carried about 42% of the load.

(*a*) SINGLE-PLATE JOINTS *FSCA*

FIG. 14.—PARTITION OF LOAD AMONG PLATES,

Before final rupture of the joint as a whole, all end-row rivets in both specimens failed. The plates fractured at the second row of rivets, except that one plate of Specimen FSCB-2 fractured half across the second row and half across the end row (Diagram *B*, Fig. 14(*b*)). About 80% of the fracture was square, and of coarse, granular texture; the remainder was of fine granular to silky texture, in part of the cup-cone and in part of the angular-shear type.

The relative displacements (slip) of the plates, observed after failure by measurements between lines scribed across the edges of the plates, disclosed that at sections where the rivets had failed, before complete failure of the joint, the slip was in excess of 0.33 in.

Double-Plate Shingle Joints FSCD.—Strains were measured along chains of 2.5-in. gage lines on the edges of the plates, as shown in Fig. 16(*a*), Diagram *A*. Over the stated range of loads, the load per rivet was found to be greatest in the two end rows and between the main plates at a butt. The load per rivet transferred directly from main plate to main plate at the middle of the joint was about the same as the average load per rivet. In general, the strain observations were confirmed by the progress of rivet scaling. Marked scaling occurred in Rows 1, 10, and 2 (in that order); little scaling occurred in Rows 4 to 7.

(*b*) DOUBLE-PLATE JOINTS *FSCB*

AND LOCATION OF FRACTURE; BUTT JOINTS

Before the joint failed as a whole, all but one of the end-row rivets failed. The plate fractures followed irregular lines which passed through rivet holes in one or more of the three rows next to an end (Diagram *B*, Fig. 16(*a*)). The fractures were in part square, with coarse, granular texture, and in part of the cup-cone and angular-shear type, ranging from fine granular to silky in texture.

Examination of the joints after fracture disclosed that wherever rivets had sheared, the relative displacement of the plates was in excess of 0.30 in.

Triple-Plate Butt Joints FSCC.—For this type of specimen, strains were measured only at selected locations along the joint, as shown in Fig. 15, Diagram *A*. The behavior of this joint was similar to that of the double-plate butt joint FSCB, in that the load per rivet was high at the ends and near the butt, and low just outside the ends of the outer (short) splice plates. In this pair of triple-plate specimens the outer splice plate was shorter than intended in the design. The progress of rivet scaling was in agreement with the computed distribution of load between rivet rows.

Along either half of the length of the joint, the twenty-seven rivets (47% of the total number) that passed through both splice plates transferred about 61% of the load from main plates to splice plates whereas the thirty rivets that passed only through the inner (long) splice plates transferred only about 39% of the load (Diagram *C*, Fig. 15).

The relatively high stress in the rivets that passed through both splice plates was reflected in the failure of Specimen FSCC-1, which failed partly in the plates and partly in the rivets, as shown in Diagrams *A* and *B*. The rivets in the end rows failed before the ultimate load was reached, and a rivet near the butt sheared at the ultimate load (Diagram *B*, Fig. 15). About 65% of the plate fracture was square, with coarse, granular texture, and the remainder was of the angular-shear type with silky texture.

Specimen FSCC-2 failed in the rivets along lines shown in Diagram *A*, although at Rivet Row 3′ (Diagram *B*, Fig. 15) a tear 4 in. long extended through a rivet to the edge in one outer main plate and a tear 0.5 in. long extended from the same rivet in the other outer main plate. Premature rivet failures occurred in five rows at each end and in two rows next to the butt (Diagram *B*).

For Specimen FSCC-1, it was found by measuring the displacement of the scribe lines which had been ruled across the edges of the joint that wherever the rivets near the end had failed the final slip was in excess of 0.33 in., and wherever rivets near the butt had failed the slip was in excess of 0.26 in. For Specimen FSCC-2, the corresponding values were 0.37 and 0.24 in.

Triple-Plate Shingle Joints FSCE.—Strains were measured at selected locations along the edges of the plates, as shown in Fig. 17, Diagram *A*. It was found that the rivets in the end rows took considerably more than the average share of the load, over the load range at which the measurements were made. The progress of rivet scaling was in agreement with the computed distribution of load between rivet rows. Between Rows 1 and 9 the scaling on the face of Plate 1 was much more severe than on the face of Plate 5, and between Rows 1′ and 9′ the scaling was much more severe on the face of Plate 5 than on the face of Plate 1.

The specimens failed partly in the plates and partly in the rivets, as shown in Diagrams *A* and *B*, Fig. 17. The rivets in the two end rows failed before the ultimate load was reached; and some rivets in the third and fourth rows sheared before final failure occurred (Diagram *B*). The plate fractures

followed an irregular course through the third and fourth rows of rivets. About 75% of the fracture was square, with coarse, granular texture, and the remainder was cup-cone or angular-shear with silky or fine granular texture. Near the ends of both specimens, wherever rivets had failed prematurely, the slip was more than 0.25 in.

Triple-Plate Half-Shingle Joints FSCF.—Strains were measured at a limited number of locations along the edges of certain of the plates as shown in Fig. 16(*b*), Diagram *A*. In order that the loads carried by the several plates may be more easily visualized, the curves of Diagrams *C* have been made the same for the near face as for the far face, under the assumption that corresponding plates deformed equally. The assumption was somewhat in error inasmuch as the strain measurements revealed some straightening of initially warped plates.

Computations based on the observed strains indicated that at the given loads a large share of the total load was taken by the rivets in the several rows at the ends of the joints, almost to the beginning of the outer (short) splice plate. At the right end the outer main plates (Plates 3′ and 5′) carried their share of the load practically undiminished from Row 21 to Row 14, whereas at the left end the load in the outer main plates (Plates 3 and 5) gradually diminished. The progress of rivet scaling was in general agreement with the computed distribution of load among rivet rows. Scaling occurred earlier and was much more extensive at the right end in Rows 21 to 19 and in Rows 16 and 15 than in other parts of the joints.

Fig. 16.—Partition of Load among Plates.

A consideration of all evidence available (strain-gage data, scaling, slip before and after failure, and premature rivet failures) would indicate that near the butts and near the ends of splices (abrupt changes in longitudinal section) the rivets carried relatively high loads.

The joints failed partly in the plates and partly in the rivets, at the end nearest to the butt of the middle main plate (Fig. 16(*b*), Diagrams *A* and *B*). As the rivets in the end rows failed progressively, more load was thrown on the rivets remaining between the end and the butt, and failure resulted. It was observed that, before final failure, rivets sheared up through the fourth row in both specimens. The greater part of the plate fracture was square, with coarse, granular texture, but in Specimen FSCF-1 about 5% of the fracture was cup-cone with silky texture. Wherever rivets failed in the left end, the slip was more than 0.31 in. for Specimen FSCF-1, and more than 0.37 in. for Specimen FSCF-2.

Comparison of Specimens

Efficiency.—The efficiency of the joints at ultimate load ranged from about 71% to 75%, as shown in Table 17, Column (21). The larger joints exhibited the lower efficiencies. There was little difference in efficiency as between butt and shingle joints of the same nominal size. The efficiencies at yield load, shown in Column (15), are 10% to 12% higher than those at ultimate load, but show the same general trend as between joints.

Elongation.—The unit elongation of the single-plate joints was about the same as that of the main plate outside of the joint (Table 17, Column (12)). The

unit elongation of the double-plate and triple-plate joints on the average was 13% less than that of the plate steel. In calculating the elongation of members containing large joints of the types considered herein, for practical purposes the modulus of elasticity of the joint may be considered to be the same as that of the member outside the splice.

Slip.—The end slip at the rivet working load is shown in Table 17, Column (11). It was observed that, on the average, the end slip for the butt joints was about three-fourths of that for the most nearly comparable lap joints (specimens of Series A having silicon-steel plates and carbon-steel rivets). Table 18 shows that, in general, the greater the amount of splice material per main plate, the greater will be the end slip between main and splice plates. These results were to be expected since, for comparable conditions, in joints having the greater percentages of splice material the splice plates were relatively more rigid.

* Butt joint. † Shingle joint. ‡ Half-shingle joint.

The load-slip relations for one of each of the double-plate joints are shown in Fig. 18. Inasmuch as the joints of Series F were practically free from the eccentricity that exists in lap joints, and inasmuch as the joints in this series were over-riveted in order to insure plate failures, it was expected that friction between plates would be more of a factor than for comparable lap joints. The difference in friction is evident from the forms of the slip curves for the joints of Series F (Fig. 18) as compared with those for Series A (Figs. 8 to 10 inclusive).

On the whole, short sudden slips, accompanied by snaps, seemed to be more characteristic of the joints in Series F than of those in other series. This behavior is attributed to frictional conditions due to the tendency for plates in a butt joint to remain more closely held together under load than is the case in a lap joint where the plates tend to separate because of bending. In a number of instances in the heavier joints and at the higher loads, sudden slip occurred throughout the length of a joint. Near the ends of the largest joints the slips were relatively large, although they had little effect on the elongation of the joint as a whole. In terms of an "effective" modulus of elasticity of the joint, these movements corresponded at the most to a change from, say, 32 to 29 million lb per sq in.

Transverse Component of Shear in End Rivets.—In this series of joints the two rivets in each end row were placed near the edges of the plate, at a gage distance of 16 in. Owing to lateral contraction of the highly stressed main plates relative to the splice plates (which, at the ends, were subjected to low stress), considerable transverse shearing deformations were induced in these rivets. Although these rivets failed at relatively low computed stresses based on longitudinal shear, the strength was reasonably close to normal when the resultant of the longitudinal and transverse shear is considered.

Shear in Rivets at Ultimate Load.—In Table 17, Columns (22) and (23), is shown the average shearing stress in the rivets at ultimate load, based both on the total number of rivets and on the number which did not fail prematurely. Although most of the joints failed primarily in the plates rather than in the rivets, it is believed that the rivets were near failure at the ultimate load; in fact, one specimen (FSCC-2) failed entirely in the rivets. The values, in comparison with those of Series A (Table 9, Column (27)) indicate that the resistance per rivet shearing surface was materially less in double shear than in single shear. However, the comparison is not direct, particularly since in Series F the plates were stressed nearly or quite to their ultimate load and, therefore, had elongated greatly and had subjected the rivets near the ends to relatively large detrusions as compared with Series A. Because failure of the rivets was partly due to detrusion, and not entirely to the direct effect of loading, the rivet shearing values in Table 17 should not be used as a general basis for establishing working stresses in double shear.

CONCLUSIONS FROM THE TESTS

Since the specimens of this investigation were designed to conform reasonably well to standards of practice, the various problems and variables are, of necessity, interwoven. For example, in Series A and F the variations in nominal length of joint involve differences in actual length, thickness (number of plates), grip of rivets, and number of rivets; they are essentially variations in size rather than length. In no case is the width of joint a variable. The conclusions in this section apply only to the conditions and range of these tests.

Herein the term "rivet strength" denotes the average shearing resistance of the rivets in a given group or joint. The strength is computed by dividing the ultimate load by the total cross-sectional area of the rivets in shear, based on the nominal diameter of rivet.

Effect of Length of Joint.—In general, at the ultimate load the greater the length of the joints the lower was the rivet strength, regardless of the method by which the length was varied (that is, difference in pitch, rivet pattern, number of rivet rows, or over-all size). However, the differences were not large, and minor exceptions arose when the influence of other factors predominated. The general effect of length of connection is summarized in Table 19. For example, for joints with carbon-steel rivets and plates, the rivet strength was only about 5 kips per sq in., or about 10%, less in joints 7 ft long (eighteen rows of rivets) than in joints $2\frac{1}{3}$ ft long (six rows of rivets); for joints with carbon-steel rivets and silicon-steel plates the difference was even less. Furthermore, it appears that small variations in length are not important in comparison with variations arising from fabrication inequalities.

As between the butt joints of different length (FSCA, FSCB, and FSCC), the longer joints not only were lower in efficiency but also they failed essentially in the rivets rather than in the plates (Table 17).

Effect of Rivet Pitch.—From the tests of Series B, in which the pitch between transverse rivet rows was the only variable, it appears that over the range investigated (3 to 6 in.) the effect of pitch was small, although the 4.5-in. pitch (4.5 rivet diameters) gave slightly higher efficiency than either the 3-in. or the 6-in. pitch.

* One-plate specimens, with exceptions noted. † Pilot tests at the University of Illinois. ‡ Two-plate specimen. § Three-plate specimen.

Effect of Kind of Rivet Steel.—As compared with strength of rivets in small joints (pilot tests) or in a direct shear test of undriven rivets, in the large joints of Series A the manganese-steel rivets performed somewhat better as regards ultimate strength than the carbon-steel rivets. Although this difference is attributed in part to the difference in actual length of joint for a given nominal length, it seems fair to credit the manganese-steel rivets with this advantage since fewer rivets are needed. For the joints of Series A, all of which failed in the rivets, the average ratio of observed strength to the assigned rivet working stress (that is, the "factor of safety") was found to be 3.73 for the manganese-steel rivets as compared with 3.52 for the carbon-steel rivets.

Effect of Kind of Plate Steel.—In the joints that failed in the rivets, the effect of kind of plate steel was not large or consistent, although the decrease in shearing strength of rivets with length was somewhat more marked in the case of the carbon plate steel than with the less ductile plate steels. There was less tendency for premature failure of end rivets with the less ductile plate steels.

Single Shear vs. Double Shear.—Although the comparison is not direct, being based on the tests of joints of Series A and F [see heading: "Tests of

Butt and Shingle Joints; Series F (Comparison of Specimens): Shear in Rivets at Ultimate Load] the indications are that the strength of a rivet surface in double shear may be as low as 80% of the strength in single shear. These indications agree with the findings in the pilot tests[8] where non-driven rivets were tested in both single and double shear.

Net Section.—An outstanding finding of these tests is that the strength of the plates in a riveted joint is not directly proportional to the area of the net section, as commonly assumed in practice. The use of fewer rivets in the end rows than in interior rows is ineffective, as shown by the tests in Series C and D. Wide spacing of the end-row rivets (near the edges of the plate) is especially undesirable; in the tests of Series F it was found that differential lateral contraction of the opposing plates at each end of the joint subjected such rivets to lateral strain which, combined with the longitudinal strain, caused premature failures of these rivets.

In tests of joints having the full number of rivets in the end row (Series C and D), the efficiency was about 10% higher when the gage was about four rivet diameters than when a gage of about three rivet diameters was used.

The experimental results bore no consistent relation to the specification requirements for determining net section. In these tests, there was little difference in strength as between joints having an end pitch of four to six rivet diameters and joints having an end pitch of two to three rivet diameters, although the specifications would assign a smaller computed net section to the latter group. Regardless of the number of rivets in the end row, the net section found by deducting the projected sectional areas of rivet holes in the first two rows correlated better with the observed strengths than did the net section computed by standard specifications. It is apparent that there is nothing to be gained by using an elaborate formula to evaluate the effect of pitch on net section for joints of this type.

Butt vs. Shingle Splices.—There was little difference in efficiency as between the butt and shingle splices of Series F. The triple-plate shingle splices require less material for fabrication than the butt splice, as shown in Table 20; this advantage, however, may be offset by the somewhat greater difficulty of field erection for shingle splices. The partition of load between the splice plates agrees fairly well with the usual assumptions in designing these splices.

TABLE 20.—MATERIAL REQUIRED FOR VARIOUS TYPES OF SPLICE; SERIES F

Description	Butt splice FSCC	Shingle splice FSCE	Half-shingle splice FSCF
Weight of splice plates, in pounds.....	850	684	496
Number of rivets....................	114	114	85

Slip.—The relative movement, or slip, of adjacent plates is of interest in connection with the behavior of riveted joints. In fact, the rivets cannot develop resistance to shear until after slip occurs. Slip is believed to be of special importance with regard to structural members subjected to repetitions or reversals of load.

The load-slip relationship may be divided into these four stages: (I) Load is transmitted by friction between the plates, and general slip throughout the joint does not occur; (II) slip begins and the rivets are coming progressively into bearing; (III) the rivets are in full bearing and the load-slip relation is linear; and (IV) plastic action and yield occur in rivets, plates, or both (see heading "The Action of Riveted Joints").

These stages of joint action are not all developed to the same extent during the loading of joints of various types. In joints having four to six rows of rivets, the end of Stage I may occur at a rivet stress of 10 kips per sq in. or less. For the single-plate lap joints of Series A, the ratios of the loads at the beginning of Stage III (as nearly as could be determined) to the rivet working loads are shown in Table 13, Columns (6) and (11).

The ratio of slip measured near the ends of the joints to slip measured at the middle of length of a lap became a constant when the rivets came into full bearing (Stage III). The ratio was a function of the length of the joints.

In the tests of Series A, the joints containing carbon-steel rivets exhibited markedly less slip than those containing two-thirds as many manganese-steel rivets. As between the various series, the slip was less for joints with full-row riveting than for joints with any other rivet pattern.

Partition of Load Among Rivet Rows.—Under the assumption of perfectly elastic behavior of an ideal joint, in joints containing more than two rows of rivets, the rivets in the end rows are subjected to more than the average load per rivet.[9] In these tests, the results of strain measurements made over the working range showed that in actual joints the same tendency exists but that inequalities arising from fabrication conditions cause irregular and erratic load partition, and that the irregularities may be large as compared with the differences in load partition called for by the elastic theory.

The following general conclusions are drawn from various phases of the tests bearing on the distribution of stress in riveted joints:

(1) At low loads (Stage I), the load partition among rivets may be controlled largely by such conditions within a joint as warping of plates, variations in initial tension of rivets, and character of the faying surfaces;

(2) After slip becomes general throughout a joint (Stage II), there is a tendency for the shearing stresses to become equalized among the rivets in the various rows, although uniform partition of load is not probable;

(3) From limited data available, it appears that in Stage III the rivets in the end rows tend to take more than the average load per rivet;

(4) Although no direct evidence is available, it seems likely that in the early part of the yield range (Stage IV), the load partition among the rivets tends to become uniform; and,

(5) In the latter part of the yield range, the amount of plastic flow in the plates is so great that the resulting elongation is sufficient to cause detrusion of end rivets. For $\frac{7}{8}$-in. rivets, this rivet failure occurs when the end slip is about 0.3 of the rivet diameter, and occurs more frequently in the longer joints and in those made with the more ductile steels. It does not necessarily indicate that these end rivets are taking more than their proportionate share of the load.

In general, although it is probable that the partition of stress among rivets is not uniform at any stage of loading, the test results indicate that an assumption of uniform partition is as reasonable as any that has been made.

Recommendations Applicable to Design

The results of these tests, together with those of other investigators, appear to warrant the following statements relative to practice in the design of riveted joints for bridge construction:

(1) Nothing is gained by an attempt to detail a tension member with a critical net area greater than about 75% of the gross area;

(2) There is no justification for elaborate formulas to calculate the effect of rivet stagger on net section;

(3) Joints should be as compact as practicable (optimum results will probably be obtained by full-row riveting with a gage of about 4.5 rivet diameters and a pitch of 3.5 to 4 rivet diameters);

(4) Statements (1) to (3) lead to the suggestion that the allowable loads on riveted tension members be based on, and expressed in terms of, stress in the gross section; and, that the net section be not less than 75% of the gross section;

(5) The practice of assuming equal shear per rivet, regardless of length of joint, is satisfactory;

(6) Except in comparatively heavy structures where reduction in size or weight of splice is important, there is little reason for using manganese-steel rivets rather than carbon-steel rivets. Owing to the greater slip that occurs in joints with manganese-steel rivets, carbon-steel rivets are preferable in members subject to stress reversals; and,

(7) Working stresses recommended for use in the design of riveted joints in bridges, for steels commonly specified, are shown in Table 21. These recommended stresses were developed from a consideration of: (*a*) The strengths of the steels as indicated by standard mill acceptance tests; and (*b*) the relations between the strengths of mill coupons and the strengths of joints of structural proportions. The relationships between the strengths, in tension, of mill specimens and the properties of structural joints, based on a study of

TABLE 21.—Recommended Working Stresses for Riveted Bridge Joints

Property	Steel	Minimum Strength in Tension of Mill Coupons, in Kips per Square Inch		Recommended working stress, in kips per square inch	Ratio
		Yield	Ultimate		
Tension in gross section of plate	Carbon	33.0	60.0	16.0	1.00
	Silicon	45.0	80.0	20.0	1.25
	Nickel	55.0	90.0	22.5	1.40
Single shear in rivets	Carbon	28.0	52.0	15.0	1.00
	Manganese	42.0	75.0	20.0	1.33
Double shear in rivets	Carbon	28.0	52.0	13.5	0.90
	Manganese	42.0	75.0	18.0	1.20

data from various sources, are as follows:

Ratio	Tension in gross section of plate	Single shear in rivets (nominal diameter)
$\dfrac{\text{Useful limit point for a joint}}{\text{Yield strength of mill coupons}}$	0.72	....
$\dfrac{\text{Useful limit point for a joint}}{\text{Ultimate strength of mill coupons}}$	0.42	....
$\dfrac{\text{Ultimate strength for a joint}}{\text{Ultimate strength of mill coupons}}$	0.75	0.88
$\dfrac{\text{Effective rivet yield for a joint}}{\text{Yield strength of mill coupons}}$	....	0.83
$\dfrac{\text{Effective rivet yield for a joint}}{\text{Ultimate strength of mill coupons}}$	....	0.55

In computing these values, the useful limit point of plates in a riveted joint was assumed to be 85% of the yield strength of the joint.

The foregoing ratios are applied to the strengths of mill coupons to obtain the effective strengths of the materials acting in structural joints, as given in Table 22. The selection of strength values for mill coupons is based on an examination of mill reports on tests of steels of the given grades. It is believed that the foregoing ratios are conservative. Inasmuch as—to avoid rejections—the mills endeavor to supply material somewhat above the minimum specified, it should be safe to take values midway between the minimum and the average. Values taken in this manner are shown in Table 22 as "expected strengths."

TABLE 22.—EFFECTIVE STRENGTHS OF MATERIALS ACTING IN STRUCTURAL JOINTS

Steel	Expected Strength in Tension of Mill Coupons, in Kips per Square Inch		Useful Limit Point (for Plates) or Effective Rivet Yield (for Rivets)				Ultimate Strength	
	Yield	Ultimate	Based on yield, kips per square inch	Based on ultimate, kips per square inch	Average, kips per square inch	Ratio	Kips per square inch	Ratio
(*a*) Tension in gross section of plate								
Carbon..........	36.3	63.3	26.1	26.6	26.3	1.00	47.5	1.00
Silicon..........	47.6	83.7	34.3	35.2	34.7	1.32	62.9	1.32
Nickel..........	59.6	94.9	42.9	39.8	41.3	1.57	71.0	1.50
(*b*) Single shear in rivets (nominal diameter)								
Carbon..........	32.6	54.7	27.0	30.0	28.5	1.00	48.1	1.00
Manganese......	49.8	81.4	41.4	44.7	43.0	1.51	71.7	1.49

To obtain the recommended working stresses for carbon plate and rivet steels (Table 21), the strengths in Table 22 have been reduced by using a factor of about $1\frac{3}{4}$ in the case of the useful limit points and about 3 in the case of the ultimate strengths. When high-strength plate steels are used in place of ordinary carbon steel, some desirable property must be encroached upon to secure the added strength. The ductility and plastic flow of these high-strength steels are less than those of carbon steel, so that there is less opportunity for stress readjustment to take place and secondary stresses become relatively more important. For these reasons, working stresses should not be increased in proportion to strength. Likewise, the values of working stresses for manganese-steel rivets as compared with those for carbon-steel rivets should be lower than their relative strengths because of the greater slip that occurs in joints containing manganese-steel rivets. The rivet values in double shear per shearing surface have been taken as 0.90 times those for single shear.

ACKNOWLEDGMENTS

This series of tests was made possible by funds supplied by the San Francisco-Oakland Bay Bridge of which C. H. Purcell, Assoc. M. Am. Soc. C. E., is Chief Engineer and Charles E. Andrew, M. Am. Soc. C. E., is Bridge Engineer. The test specimens were designed by Ralph A. Tudor, Assoc. M. Am. Soc. C. E., Senior Bridge Engineer, under the direction of Glenn B. Woodruff, M. Am. Soc. C. E., Engineer of Design. Those acting in an advisory capacity in the development of the test program were C. F. Goodrich, Chief Engineer, American Bridge Company; Jonathan Jones, Chief Engineer of Fabricated Steel Construction, Bethlehem Steel Company; Leon Moisseiff, Consulting Engineer; and Wilbur M. Wilson, Research Professor of Structural Engineering, University of Illinois, all Members of the Society. The pilot tests were made under the direction of Professor Wilson.

The specimens were fabricated under contract at the Ambridge plant of the American Bridge Company from steel manufactured at the Homestead plant of the Carnegie-Illinois Steel Corporation. Of the coupons taken at the time the specimens were manufactured, about one-third were tested by the Carnegie-Illinois Steel Corporation under the supervision of J. M. Bailey, Principal Steel Inspector for the San Francisco-Oakland Bay Bridge; the remaining coupons were tested at the University of California.

The static tests on large joints were made in the Engineering Materials Laboratory of the University of California, during the period 1935 to 1937. The University of California was represented by Charles Derleth, Jr., M. Am. Soc. C. E., Dean of the College of Engineering, and Raymond E. Davis, M. Am. Soc. C. E., Professor of Civil Engineering, in charge of the Laboratory. The following members of the staff of the Engineering Materials Laboratory, University of California, participated in the conduct of the tests and the analysis of the results: J. L. Banville, E. H. Brown, Harmer E. Davis, Assoc. M. Am. Soc. C. E., H. D. Eberhart, Jun. Am. Soc. C. E., E. J. Garbarini, Jun. Am. Soc. C. E., Norman Haavik, J. W. Kelly, M. Am. Soc. C. E., Alexander Klein, Assoc. M. Am. Soc. C. E., J. F. Ryan, G. E. Troxell, M. Am. Soc. C. E., and E. L. Whittier. During the progress of the work, the San Francisco-Oakland Bay Bridge was represented by C. C. Winter, Assoc. M. Am. Soc. C. E., E. B. Payne, and R. L. Richardson, Juniors, Am. Soc. C. E.

Publication of the paper was made possible by financial assistance granted by the Engineering Foundation.

DISCUSSION

Charles F. Goodrich,[13] M. Am. Soc. C. E. (by letter).—It is the writer's opinion that the two groups of tests on structural riveted joints, made in connection with the design and construction of the San Francisco-Oakland Bay Bridge, are unequaled in their contribution to the knowledge of the behavior of such joints. Most of those who studied Professor Wilson's paper on "Fatigue Tests of Riveted Joints"[8] were considerably disturbed by the rather low fatigue values obtained, especially for the higher strength steels; but they were more especially disturbed by the low unit stresses at which slip occurred in the high-strength, or the so-called manganese, rivets. It seems to the writer that, in so far as static loads are concerned, the results of the present tests confirm, rather than disturb, one's confidence in riveted joints.

As the factor of fatigue is absent from the tests described in this paper, its authors quite properly have based their conclusions on the static tests of large, full-size specimens. This discusser would emphasize that there is considerable danger in projecting laboratory results on small specimens into the design of structures without a sufficient study of other mitigating factors, such as frequency of maximum loads, yielding of joints and other members and recovery between loads. Literature on projecting laboratory studies on fatigue into actual structures is sadly lacking. The profession needs such interpretation.

The authors have thrown considerable light on the action of riveted joints by considering four stages of joint action: Stage I, in which static friction prevents slip, the end of this stage being at the point at which slip at the middle of the joint takes place; Stage II, in which slip occurs until the rivets come into bearing; Stage III, in which rivets and plates deform elastically; and Stage IV, in which yielding of the plates, rivets, or both, occurs until either plate fracture or complete shearing of the rivets results.

Comparing joints of carbon rivets with those of manganese rivets, in which the number of rivets is in proportion to their shearing values, the authors, confirming Professor Wilson, find the average rivet stress at the end of Stage I much lower for manganese rivets than for carbon rivets (roughly, one-half) but, as the stages progress, the manganese rivets come into bearing and "catch up." At the beginning of Stage III they are roughly equal, and in Stage IV the manganese rivets have "come into their own" and their value, as compared to the value of carbon rivets, is about proportional to the strengths of the materials.

Regarding this matter of slip, it seems evident that engineers can no longer consider that the friction between the plates of a joint, due to tension developed by the rivets, is a measure of the joint value, even with carbon rivets in carbon plates—especially as working stresses are being continually increased as structural steel is improved in quality and strength.

With respect to high-strength steels and high-strength rivets, these tests have proved that friction between the plates disappears at stresses at or below the working stresses which are reasonable with such steels, and slip occurs in the connections of a member probably either before, or as soon as it receives its full-load stresses. As the rivets come into bearing at these low stresses, it would seem advisable to have the rivets fill the holes as nearly as possible. The writer believes that the optimum in this respect, with due regard to fabrication costs, has about been reached. Clearance between rivet and rivet hole cannot be reduced without causing expensive difficulty and delays in entering. Furthermore, the limit has about been reached in human strength to handle heavier, higher-pressure, rivet guns. The writer believes that the driving technique now being used on large structures by reputable contractors, under competent inspection, secures results that are reasonably satisfactory. Special endeavor to upset the rivets to fill the holes more completely was made in the case of the San Francisco-Oakland Bay Bridge, including investigation of sample drivings, but it is doubtful if it resulted in much better filling of holes in the actual structure than is accomplished in the usual best practice.

---

[13] Chf. Engr., Am. Bridge Co., Pittsburgh, Pa.

There is a balance in economy that must not be ignored. If structural engineers continue to increase unit stresses and then begin to worry about rivets not entirely filling the holes and several other points of workmanship, they may well question whether economy has really been effected. The rivets in the joints of the tension tests on large riveted joints, presented in this paper, were driven under usual shop practice. Some of the rivets were quite long and it is doubtful whether they filled the holes any better than usual; and yet, the joints all showed consistently excellent results. In fact, they were so consistently good as to inspire the writer with fresh confidence in driving technique and in riveted joints generally, especially large butt or shingle joints, data on the strength and behavior of which have been so sadly lacking until now. These tests confirm, in large joints (as have all similar previous tests on smaller specimens), the peculiar capacity of structural steel to transmit stress efficiently and safely from one part to another by means of rivets in shear and bearing.

The tests are a distinct warning that the connections of members subject to reversal of stress must be over-riveted, especially when using high-strength rivets. There are not many members subject to reversal, however, in which stresses are large enough to demand high-strength rivets. Continuous structures are likely to have several members subject to reversal, either at the design loads, or at a future over-load. Such members should be connected with an ample number of rivets to prevent slip—perhaps more than have heretofore been used.

The authors have arrived at some rather startling conclusions, one of which has been suspected by some engineers—namely, that designers have been wasting effort trying to maintain an optimum net section at the ends of connections or splices by the use of considerably fewer rivets in the end rows. The tests demonstrate that this is a source of weakness, in that "wide spacing of the end-row rivets (near the edges of the plate) is especially undesirable; * * * differential lateral contraction of the opposing plates at each end of the joint subjected such rivets to lateral strain which, combined with the longitudinal strain, caused premature failures of these rivets." Furthermore, the authors state: "The experimental results bore no consistent relation to the specification requirements for determining net section," and that "It is apparent that there is nothing to be gained by using an elaborate formula to evaluate the effect of pitch on net section for joints of this type." The authors have gone so far in this matter as to offer the proposal that "the allowable loads on riveted tension members be based on, and expressed in terms of, stress in the gross section"; then they propose that the members be so detailed "that the net section be not less than 75% of the gross section."

Based on their considerations of the tests, the authors have offered several recommendations, applicable to design, in addition to the one already mentioned regarding net *versus* gross section. It seems to the writer that these tests and recommendations should be given serious consideration by all structural engineers. There is room in this discussion for only a few points.

The authors have tabulated their recommended working stresses for use in the design of riveted joints in bridges, for steels commonly specified (see Table 21). The working stresses for carbon, silicon, and nickel steels are given respectively as 16.0, 20.0, and 22.5 kips per sq in. on the gross section. Assuming that the net section is the minimum recommended by the authors (namely 75% of the gross), these working stresses give unit stresses on the net section of 21.3, 26.7, and 30.0 kips per sq in., respectively. These unit stresses are quite high for general use in bridge design and are scarcely to be recommended for railroad bridges, light highway bridges, or most heavy highway bridges; and they are, perhaps, applicable only to bridges in which the dead load constitutes a large proportion of the total load—say 50 per cent. They are less, however, than was specified for the San Francisco-Oakland Bay Bridge.

The writer questions whether the authors have not based their recommendation of gross section unit stresses for tension members and 75% ratio on their large tension tests only, which are made up of plates alone. Have they also considered the effect of this recommendation on members built of rolled sections or a combination of rolled sections and plates? Consider, for instance, the simple case of a single angle. Any angle that has one hole for a $\frac{7}{8}$-in. rivet will have left a net section considerably greater than 75% of the gross. Therefore, a unit stress that is based on balancing the 75% ratio is likely to waste material in rolled shapes and even in plates. The gross-section-unit-stress method would be very easy to use, of course, but it would either call for too tight a ratio, gross to net, or it would make it all too easy to waste material and do away with all ingenuity on the part of designers and detailers directed toward maintaining as large a percentage, net to gross, as possible. It scarcely seems possible to find a unit stress based on gross section that will fit various conditions and not waste material.

The authors recommend a somewhat smaller ratio of increase in working stresses in the high-strength steels, as compared with those for carbon steels, than the ratios of minimum yields or tensile strengths of the mill coupons. Ratios of working stress of 1.25 and 1.40 are assigned for silicon and nickel steels, respectively, and 1.33 for manganese rivets, as compared with 1.00 for carbon steel. The authors' conservatism does not seem to be borne out by the results of the tests but is based rather on theoretical considerations as, when high-strength steels are used, some desirable property, such as ductility, plastic flow, and opportunity for stress distribution, must be sacrificed. The tests seem to confirm, rather than upset, the established custom of basing the unit-stress ratios on the yield ratios. Although fatigue may be a reason for a decreased ratio, such a reason must be kept separate from deductions resulting from the tests under discussion.

There is a factor (which may be called a safety factor) that engineers are prone to lose sight of—namely, that the steels, as produced, have actually better physical properties than the specified minima, because the mills, in order to avoid rejections, "play safe" and aim to stay well above the required minima. The average minima run, as the authors state, from 5% to 10% above the required. This tendency to "play safe" is greater in the production of high-strength steels than the ordinary carbon steels because of the greater monetary loss of rejections.

It seems to the writer that both Professor Wilson's tests[8] and those described in this paper have proved conclusively that rivets are not twice as strong in double shear as in single shear, and that specifications should be written to agree with what seems to be a well-established fact. The authors have recommended a ratio of 1.8.

The tests appear to justify Recommendation (5), which states that the practice of assuming equal shear per rivet, regardless of length of joint, is satisfactory. This is a very reassuring conclusion and inspires further confidence in large riveted joints.

The writer cannot agree with Recommendation (6), which states that, except in comparatively heavy structures where reduction in size or weight of splice is important, there is little reason for using manganese-steel rivets rather than carbon-steel rivets. The authors seem to connect this recommendation to the weight of splice material only, and to forget the economies to be obtained by using manganese rivets, not only in splices, but in the connections of members to gussets, where considerable economy is possible due to saving of material and number of rivets. Furthermore, the use of manganese rivets makes for shorter connections which are recommended by the authors. There are genuine difficulties involved in detailing connections for high-strength steels without a corresponding high-strength rivet. The writer believes that there is a need for high-strength rivets, although perhaps not exactly of the same chemical constituents as were used for the rivets for the San Francisco-Oakland Bay Bridge and in the tests presented in this paper. A somewhat more usable, perhaps softer, rivet will probably be developed for main members, such as will match silicon steel rather than nickel, as it seems likely that nickel-steel will be rarely used as compared with silicon, which bids fair to continue in wide use. A rivet that can be used with a steel of 45 to 50 kips per sq in. would seem to be the most desirable.

The writer wishes to congratulate the authors on the completion of an important series of tests, and on their careful and scientific analysis of them, resulting in material addition to the knowledge of the behavior of structural riveted joints, and in data which should (and undoubtedly will) be used widely by structural engineers in the preparation of specifications.

Frederick P. Shearwood,[14] M. Am. Soc. C. E. (by letter).—The distribution of the loads in the rivets and the stresses in the material of large riveted joints is one of the problems that, on account of its complexity and the many indeterminate factors which enter into its resistance, have been avoided by mathematical theorists; and these joints have been designed by simple empirical rules and the designer's common sense or judgment. The adequacy of riveted joints proportioned on the assumption that all the rivets in a joint are equally stressed is a confirmation of the "limit design theory" as presented by J. A. Van den Broek,[15] M. Am. Soc. C. E. There can be little doubt, and this paper confirms it, that it is the ductility of the material which enables the resistance to be safely distributed before the end rivets lose their resisting value.

---

[14] Cons. Engr., Dominion Bridge Co., Ltd., Montreal, Que., Canada.

Although careful designers have had to adopt the practice of disregarding the uneven distortion of material in a riveted joint, they have realized that this is not a really satisfactory method and these tests, and the able presentation of them, are most timely and useful contributions to structural engineering. Many of the findings should be applied to modify standard specifications and practice and so utilize more efficiently the resistance of these joints.

To compute, accurately, the stresses in each rivet of a joint it would be necessary tó know the exact clearance in the holes, the exact frictional resistance between all the surfaces in contact, and the relative deformations due to shear bearing and extension of the plates. These and some other factors are rather indeterminate and make the problem unsolvable; but, to visualize the approximate progressive action as a joint is loaded, is very desirable.

The action of riveted joints as described in the beginning of the paper does not appear to be possible if there is clearance in the holes and, unless the frictional resistance is elastic. Considering that there is clearance and that the friction is not elastic, all the stress must be resisted by the first row until it slips, because the strains in the connected plates must be alike if no movement occurs between them. For instance, in Fig. 19(*a*), if no movement occurs the strain in the two plates between Rivets *A* and *F* must be equal, and therefore Rivets *B C D* and *F* are redundant until the plates slip at *A* and *F* when *B* and *E* will resist the surplus stress; and the strain in the plates between *B* and *E* will be equal until they slip and *C* and *D* come into action. The condition when the load is just below the total frictional resistance of all the rivets will be as shown in Fig. 19(*a*) where Rivets *A* and *F* have slipped an amount equal to the difference in the strains in the upper and lower plates from *A* to *F*; whereas the slip at Rivets *B* and *E* is equal to the difference in strains from *B* to *E*. If the load is now increased so as to overcome the friction of all the rivets, the plates will slip until the end rivets come to a bearing and shear in them resists further movement. This condition is shown in Fig. 19(*b*), which shows that the interior rivets still have considerable clearance and so are only resisting by friction. If the load is doubled (see Fig. 19(*c*)), there will still remain a small clearance at Rivets *C* and *D*, and most of the extra load is taken by the first rows, *A* and *F*, and only a small amount by *B* and *E*.

Figs. 19(*d*) and 19(*e*) show the relative position of the plates when the rivets are stressed according to Fig. 1. In Fig. 19(*d*) the general slip is made so that Rivets *A* and *F* are strained to the correct amount to resist 25 000 lb in shear,

FIG. 19

and it is seen that the other rivets still have clearance and, therefore, should not resist except by friction. In Fig. 19(*e*) the general slip is made so that Rivets *C* and *D* are strained to resist the 2 500 lb in shear, when it becomes evident that the other rivets are strained far above the amounts given by this theory. If the clearances in the holes are eliminated and the friction is elastic, the loads on each rivet will agree closely with this elastic theory; but in this case, as there is no clearance, there should not be any early sudden slip as shown by the tests. Fig. 19(*f*) is an illustration of the rigid plate theory (general practice) which shows that the distortions at the holes are altogether at variance to the assumed shears.

The unit distortions, frictional resistances, and clearances used in making these diagrams are only approximations; but the diagrams may help to visualize what takes place in these joints, and may assist in interpreting the tests.

The tests show that considerable deformation can occur in the rivets and holes at the ends of these joints, and that it is enough to bring the interior rows into considerable effective resistance before the strength of the outer rivets is destroyed. The total slip at the end rivets, according to these tests, may amount to as much as $\frac{3}{8}$ in. before failure occurs. This is far more than the clearance in the holes can possibly be, and must be accounted for by considerable distortion from bearing strains in the rivets and plates, shearing and bending in the rivets, and bending in the plates around the end rivets. It seems likely that the fracturing of the plates through the end rivet holes may be due primarily to initial failure around these holes rather than to the uniformly high stress in the net area of the entire plate. This may indicate why it is better to increase the number of rivets in the end row, thereby reducing the strains around these holes, than to decrease the average unit stress in plates by decreasing the number of holes in the end section.

The tests were all made with continuous loading and the effect of intermittent loading and stress reversals have not been considered. It seems logical and probable that much of the slip allowed by the clearance in the holes and due to overcoming the frictional resistance, would be recovered on releasing or reversing the load, if the stresses in the plates between the rivets which have slipped and the addition of the reverse load exceeds the frictional resistance of the rivets. Therefore, when reversals must be resisted, the least of the alternative stresses in a joint (with clearance in the holes) should not greatly exceed the frictional value of the first row of rivets if deterioration of the joints is to be avoided.

Clearance in the holes has often been considered as a means of relieving the concentration of stress in the end rivets; but these tests and consideration of the action in them appear to show the reverse, and unless a great proportion of the rivet resistance is due to friction, a better distribution is obtained without clearance. Cold-driven rivets may be the best means of obtaining this result as very little cooling occurs after the driving pressure is removed. Experience with cold riveting in tank work would seem to prove that such rivets do fill the holes thoroughly.

The authors' conclusions emphasize, indirectly, the importance of accurate workmanship because such faults as poor matching of holes must increase the amount of slip, and overstrain the vulnerable rivets. Unstraightened material, etc., must decrease the contacting surfaces and so decrease the friction between the plates. This feature suggests that drilling should give some advantage over punching, as the latter must deform the plates to some extent and so decrease the area of contact between surfaces.

Recommendations (1) and (2) of the paper are of great importance. For some time, there has been a fairly general feeling among designers that the spreading of rivets to save section area was more of a competitive effort to save metal and meet specifications than to gain genuine strength. These tests appear to show quite definitely that nothing is gained by doing it. Recommendation (5) seems rather too broad as these tests and theoretical considerations indicate that the strain in the end rivets must be increased as the length of the joint is increased. It also conflicts with reasons implied by Recommendation (3).

The magnitude and inequality of the distortions in riveted joints, as found by these tests, again emphasize that much of the designing cannot be based entirely on the elastic theories, and they also indicate how useful the ductility of steel can be in offsetting the errors in the assumptions used in designing and in safeguarding the mistakes and abuses of workmanship. The ductile and the excess elastic properties of steel must often function, but seldom are acknowledged.

JONATHAN JONES,[16] M. AM. SOC. C. E. (by letter).—The engineers of the San Francisco-Oakland Bay Bridge performed a notable service when they appropriated the sum required for a testing program on this large scale. Very seldom can a fraction of such a sum be found for structural research. One of the probable results of this report, however, is that it will justify reliance in future (as other phases of the riveted joint are investigated) upon smaller specimens and less expensive programs. That is, in future it may be adequate to reason from small to large, now that data have been presented on a project that covered both.

In accordance with the desires of those who formulated this program, considerable effort was made to acquire a knowledge of the details of the behavior of these joints prior to their failure. This behavior has been explained clearly in general terms, and for these specific joints certain intermediate loads, called "useful limit point" and "effective rivet yield," have been defined and recorded. This represents an inquiry as to whether such intermediate, rather than the ultimate, loads shall be the basis for determining design loads, by analogy with the customary use of tensile yield point, rather than ultimate strength, of main material.

The answer appears to be in the negative; the record suggests that the intermediate points in question are not so sharply defined, and not so important to structural behavior, but that the ultimate capacity of a joint, much more readily and certainly ascertainable, will suffice for designing.

Examining the lap joints (Table 5) which failed in the plates, one finds that the yield ratio (Column (14) divided by Column (18)) is 0.61 and 0.54 for $\frac{3}{4}$-in.

---

[16] Chf. Engr., Fabricated Steel Construction, Bethlehem Steel Co., Bethlehem, Pa.

and ⅝-in. plain carbon plates, and 0.75 to 0.62 for plates in joints, as against 0.64 and 0.56 for the mill coupons corresponding respectively thereto. This ratio is expected to be 0.55 to 0.60 in structural steel. Therefore, if the engineer designs for a certain factor of safety against failure of plates in a joint, he will automatically have an adequate factor against joint yield point.

Examining the lap joints (Table 9) which failed in the rivets, one finds that the rivet-yield ratio (Column (19) divided by Column (26)) is 0.57 to 0.71 for carbon rivets (1 in 5 being less than 0.60) and 0.56 to 0.67 for manganese rivets (1 in 9 being less than 0.60). Again, therefore, if the structural engineer designs with respect to breaking loads he will be in a usual relationship with the "effective rivet yield." The same comment holds true for the ratio between the yield load and the ultimate load for the more complex joints of Table 17, in which silicon plates were connected by carbon rivets.

On the basis of this comment, designers may base riveted joint design upon the breaking strengths determined in tests past, present, and future, with no fear of insufficient protection against some intermediate stage of yield. There is an important exception—the effect of pulsating or alternating loads upon joints which may slip readily; but this is a subject for direct testing in fatigue, rather than for reasoning from phenomena observed in static testing.

It is gratifying that these tests should have led to the authors' fifth conclusion that "the practice of assuming equal shear per rivet, regardless of length of joint, is satisfactory." Their record shows that this may be said of all of the rivets in any one joint. It is not so certain that it should be taken to mean that the same unit shear may be assumed for all of the rivets in a very long joint as for all of those in a very short one. Rivet strength in 7-ft joints was 10% less than in 2-ft joints (heading "Conclusions from the Tests: Effect of Length of Joint"). This is not a great difference, so long as specification values are not based on the results of the long joints. Rather than do that, the writer would urge that they be based on short joints and slightly reduced for larger ones, since there are possibly thousands of 2-ft joints designed and fabricated for every one of 7 ft.

Before any value can be assigned to a rivet, there must be knowledge of the relation between the ultimate shearing strength of a driven rivet, and the tensile strength of the bar from which it was manufactured. Neither this report nor the pilot test report[8] deals satisfactorily with this important ratio, because it would require that an individual heat be followed through from tension testing of the bar to shear testing of a joint, instead of using averages; and it would require starting with an annealed bar for the tensile test because the cooling conditions make "as-rolled" bars from the same heat so variable in tension test.

This has been done and reported elsewhere;[17] and the writer, in consequence thereof, approves the authors' proposed 15 kips per sq in. shear for carbon rivets (if tied to 52 kips per sq in. specified minimum tensile strength) and their 20 kips per sq in. shear for low-alloy rivets (if tied to 68 kips per sq in. specified minimum tensile strength, annealed). These should be safe values for static loads, as in buildings, and for bridge design if tied in to live loading somewhat in excess of that now operating.

---

[17] Report on Silico-Manganese Rivet A195-36T to Subcommittee II of Committee A-1, American Society for Testing Materials, by the Section on High-Tensile Rivet Steel, 1938.

Similar shearing tests (not published) have been made on eleven different compositions of low-alloy rivet steel, ranging from 64 to 83 kips per sq in. in annealed tensile strength. It was found that the ratio "shearing strength of driven rivet to annealed tensile strength of bar" was as low as 0.90 and as high as 1.065. The tests indicate that this ratio should be determined for each particular rivet steel proposed for use; with that information at hand, and with the data of the authors' experiments, the breaking strength of any structural joint in which the rivets are the weaker element will be predicted easily. The same is not true of the behavior of the plate material in joints that are adequately riveted or over-riveted.

Most, if not all, of the tension members in riveted bridge trusses, now standing, have been detailed on a certain assumption which these experiments tend decidedly to disprove. That assumption is that the safe strength at any right section is proportional to the net area existing on that section. Accordingly, economy of main material has been realized by so detailing as to start with a reasonable minimum number of rivet holes across any general section through the body of the member (tack rivets, attachments of diaphragms, etc.) and, on entering a splice or connection, to omit more and more holes as stress is passed through rivets into the splice or connection plate, until in the heart of the splice or connection as many holes are omitted from a section as the prescribed minimum spacing of rivets will allow.

In a typical chord of a bridge built in 1939, for instance, the computed net section at the entry into a connection is 85% of the gross, and in the heart of the connection it is found to be 73%, the difference being accounted for by stress unloaded into the connection plates. The evidence of the authors' tests is that the section of 85% net area is actually no stronger than that of 73% net area, the reason being found in stress paths and strain effects.

It is natural to inquire at once as to what extent existing bridges are deficient in capacity, as compared with the designers' intention, on the evidence of these experiments. To that end the writer has had computed the factors of safety of all of the splices tested in those experiments, dividing their "adjusted" yield loads and "adjusted" breaking loads by the working loads which would be permitted upon them under the present bridge design specifications of the American Railway Engineering Association (A. R. E. A.). By "adjusted" load is meant the actual experimental load, reduced in the ratio of the minimum yield point, or ultimate strength, of steel permitted under A. R. E. A. specifications, to the corresponding coupon value on the material used in these experiments. The resulting factors of safety, therefore, are presumed to represent the least that could occur in practice, and are less than any average values that might be assumed from any average strength of material as supplied.

These "adjusted" factors of safety are shown in Tables 23, 24, and 25, corresponding respectively to Tables 5, 9, and 17. Each line in these tables represents the average of two identical test specimens. The values in Column (5), Table 23, are obtained from Table 1 by multiplying Column (4), Table 1, by Column (14), Table 1. The adjusted yield load (Column (6), Table 23) equals $\frac{\text{Column (5)} \times 33}{\text{Column (4)}}$, to reduce to the value of the weakest permissible material. The adjusted ultimate load (Column (9), Table 23) equals $\frac{\text{Column (8)} \times 60}{\text{Column (7)}}$, to reduce to the value of the weakest permissible material.

* Column (2), net area by Specifications of American Railway Engineering Association, 1938, Par. 409; Column (3), the same, multiplied by 18 000 lb per sq in.

† No rivets.

Values for allowable load in Column (6), Table 24, are equal to Column (5) × 13.5 for carbon rivets and Column (5) × 18 for manganese rivets. The values in Columns (7) and (10), Table 24, copied from Table 4, are not very satisfactory because they are averages of more than one heat. These values were obtained from 95 "as-rolled" rods for carbon rivets and from annealed rods for manganese rivets. The adjusted yield load (Column (9), Table 24) equals $\frac{\text{Column (8)} \times 28}{39.6}$ for carbon rivets; and $\frac{\text{Column (8)} \times 38}{49.2}$ for manganese rivets; 28 kips per sq in. is the specified minimum yield point under specifications of American Society for Testing Materials (A. S. T. M.) A141–36 and 38 kips per sq in. (annealed) is the specified minimum yield point under A. S. T. M. Specification A195–39T. The adjusted ultimate load (Column (12), Table 24) equals $\frac{\text{Column (11)} \times 52}{57.2}$ for carbon rivets and $\frac{\text{Column (11)} \times 68}{74.7}$ for manganese rivets; 52 kips per sq in. is the specified minimum ultimate strength under A. S. T. M. Specification A141–36 and 68 kips per sq in. (annealed) is the specified minimum ultimate strength under A. S. T. M. Specification A195–39T.

In Table 25, the adjusted ultimate load for the plates (Column (9)) equals $\frac{\text{Column (8)} \times 60}{\text{Column (6)}}$, and for rivets (Column (10)) equals $\frac{\text{Column (8)} \times 52}{\text{Column (7)}}$, 60 kips and 52 kips being the minimum ultimate strengths for plates and rivet

bars specified by A. R. E. A. materials specification. The factor of safety at the yield point was not computed because the joint yield point was difficult to relate to the plate and the rivets, respectively.

* Columns (2), (4), and (5), by Specifications of American Railway Engineering Association, 1938.

For lap specimens failing in plates (Tables 5 and 23), the safety factor for adjusted yield load varies from 1.69 to 2.17 and that for adjusted ultimate varies from 2.85 to 3.51. For lap specimens failing in the rivets (Tables 9 and 24), this safety factor for adjusted yield load varies from 1.92 to 2.92 and that for adjusted ultimate varies from 3.36 to 3.95. For butt and shingle joint specimens (Tables 17 and 25), this safety factor for adjusted ultimate varies from 2.61 to 2.79. As against these may be set the minimum factors of safety intended by the specification writers, $\frac{33}{18} = 1.83$ for yield load, and $\frac{60}{18} = 3.33$ for ultimate.

One interesting circumstance is that, as regards "adjusted yield load," the lap specimens CCCO and DCCO, both of them plain material without any holes or rivets, are more deficient in factor of safety than any of the riveted specimens. This is not true as regards ultimate strength. Deficiency in joint yield point, therefore, is not to be taken too seriously as a criticism of rivet arrangement.

The ratio $\frac{1.69}{1.83} = 92.3$ per cent. Therefore, existing margins against yield point, in carbon steel design, are apparently never below the intention by more than 8%, and seldom below at all; but $\frac{2.85}{3.33} = 85.5\%$ and $\frac{2.61}{3.33} = 78.3\%$; and therefore existing margins against ultimate, in carbon steel design, are occasionally as much as 15% below the intention, and in silicon steel they are habitually lower yet. Viewing this latter statement from another angle, it is as if carbon steel members had occasionally been designed for $\frac{18}{85.5} = 21$ kips per sq in. and silicon steel members for $\frac{24}{78.3} = 30.6$ kips per sq in., neither of which values would meet with general approval in a specification for a new bridge.

The authors wish to place tension-member design on a basis more in accord with their test results, and at the same time they apparently desire not to add too greatly to the current costs of bridgework. Accordingly they recommend: (1) That tension members be designed for gross section; (2) that 25% be taken out of the critical sections and no more be permitted to be taken out at other sections; and (3) that the allowable unit stress on gross section of carbon steel bridge members be 16 kips per sq in.

The writer believes that the first recommendation involves too many difficulties to be acceptable. For instance, many tension members are being built to-day with top and bottom cover plates, pierced with oblong holes, say, 12 in. wide, to permit access. These cover plates are reduced in net width by nearly 50 per cent. Other irregularities are encountered in detailing. Designers will have to treat such cases on the basis of the picture that exists, and the writer feels that a net-section basis, however modified, will necessarily be retained.

Since additions on the order of 10% to 15% to the gross section of riveted tension members are not acceptable economically, designers will begin a search for expedients whereby no such additions need be made if the findings of these tests are accepted. The authors realize this, and they have offered such an expedient, namely (see Recommendation (3)), that a gross unit stress of 16 000 lb per sq in., which is equivalent to 21 333 lb per sq in. on a 75% net section, be substituted for the 18 000 lb per sq in. of net section found in current specifications.

As one argument for such increase, the authors cite the excess of coupon strength they have found over the specified minimum, amounting to 10% at yield point and 5% at ultimate. To the writer this excess seems not available for design purposes. It is true that he has seen few yield-point reports that did not exceed the specified minimum, but he has seen many reports of ultimate tensile stress that were a few hundred pounds under or a few hundred pounds over. To depend, definitely, on all steel being, by some percentage, stronger than the specification requires is illusory. Designers should continue to assume that steel of the minimum permitted strength may be built into any critical part of their structures.

Another argument for increasing allowable unit stress in a joint is found by the authors in the fact that the ratio, $\frac{\text{Breaking load per square inch}}{\text{Coupon strength}}$, is greater than 100% (103.6 and 105.7) for Specimens CCC5 and DCC5 (all holes out), whereas it varies from only 83.3 to 96.7 for the nine Specimens CCC2 and DCC2 (two end holes). These findings are confirmed by E. L. Gayhart[6] in the following words:

> "A plate failure through the net section of full-row chain riveting may be expected to show a strength in excess (possibly 10 percent) of the theoretical value. The omission of alternate rivets in the outer row causes a loss of strength in the net section failure as compared with full-row riveting, and may even show less than theoretical strength."

Further confirmation is found in wide-plate tests by Wilson, Mather, and Harris[18] in which it appears that riveted lap joints with rivet spacing the same in all rows showed unit strengths on net section exceeding the coupon strength by 6.5% for two rows and by 7.5% for four rows. Other joints with certain rivets omitted from the outer rows, while their total capacity was thereby increased, showed less unit strength on net section than the coupons.

However, it will be noted that these reported increases of 3.6% to 10% over coupon strength, in specimens with all holes out, do not check with the authors' proposed increase from 18 000 to 21 333, or 18.5%, in working stress.

The increase over coupon unit strength was obtained by the authors (in Specimens CCC5 and DCC5), by Gayhart, and also by Wilson, Mather, and Harris on specimens with closely and uniformly spaced gage lines, creating a very straight and uniform flow of stress. Practically, such a condition cannot exist in built-up members, where flange angles, for instance, prevent this perfectly uniform spacing of gage lines. Before the results of Specimens CCC5 and DCC5 can be taken as a basis for design, they should be checked by similar specimens, except that the spacing of the gage lines should have variations up to at least an inch; and by still other specimens in which most of the 25% area deducted should be collected in one hand hole.

---

[18] "Tests of Joints in Wide Plates," by Wilbur M. Wilson, M. Am. Soc. C. E., James Mather, and Charles O. Harris, Eng. Experiment Station, *Bulletin No. 239*, Univ. of Illinois, 1931, Table 9, p. 44.

Furthermore, the even spacing of gage lines is not the only factor in favor of Specimens CCC5 and DCC5 in these tests. Comparing their designs (see Fig. 3), the distance from center of splice, where both plates are carrying the same unit stress, to the extreme rivet row where the stress in one plate is doubled and in the other reduced to zero, is seen to be 2 in. for Specimen CCC5 and 6 in. for Specimen CCC2–2. It is 6 in. for Specimen DCC5 and 9 in. for Specimen DCC2–3. Is it possible that the effect of differential plate stretch, elsewhere cited by the authors as a reason for failure in the end row, was here a little favorable to Specimens CCC5 and DCC5? It would seem that further tests are indicated, gradually increasing the pitch between the two rows of Specimen CCC5 and thus increasing this differential stretch.

Furthermore, some tests should be run in double shear. A factor which should thus be eliminated is the influence of bending on lap specimens. Whatever this factor may be, it may have been different on the short joint, CCC5, and the longer joints of the CCC2 series.

Therefore, the entire question of specification revision should await a more complete range of tests, simulating a number of practical arrangements of parts (plate with two flange angles, etc.) in which it is impossible to achieve an ideal stress path. It would seem that lighter and smaller specimens would serve this purpose.

Until further information is thus obtained, it would be premature to adopt a tensile stress of 16 kips per sq in. of gross section simply because of the behavior of the more or less ideal Specimens CCC5 and DCC5.

The more probable, although only implied, basis for the authors' recommendation as to unit stress is that the factors of safety corresponding thereto have been shown (as outlined in the first part of this discussion) to be all that exist in at least some parts of some existing bridges (and can at any time exist, under current specifications); and these bridges appear to be satisfactory. It seems doubtful that this will be a general attitude. It is possible that, in course of time, designers might adopt, and detailers would welcome, the principle of taking all holes out of all rows in splices and connections. It seems less likely that they will pass quickly from 18 to 21 kips per sq in. as a permissible unit stress on such sections.

It may be of interest to cite a test made at Lehigh University, in 1939, by Bruce G. Johnston, Assoc. M. Am. Soc. C. E.[19] A bar 17.5 in. wide was reinforced with a pair of pin plates attached by fillet and plug welding. In front of the pin, the pin plates tapered toward the center of the bar.

The welds at the forward end of the pin plates, where the differential elongation appeared in the authors' tests to be so severe on rivets, showed no distress. These fillets were equal to, but not in excess of, the requirements of the American Welding Society Specifications for Welding of Bridges. After failure (through bolt holes in the body of the bar), the whitewash had not scaled away from these welds.

---

[19] *The Welding Journal*, Am. Welding Soc. August, 1939, p. 253–5.

There is an interesting lead here toward an expedient for joint design to meet the situation revealed by the authors' tests—namely, before entering a riveted joint or splice, to weld on a reinforcing plate of such dimensions that full gross section can be used in the design, and full-row riveting can be used throughout the joint. This expedient must be regarded with caution because (*a*) its effect upon strength in fatigue remains to be proved by test, and (*b*) fabricators are not prepared to do welding on main members in riveted construction except at relatively high cost. Nevertheless, for long members and for fairly steady stresses, this expedient appears to the writer more valid than a considerable upward revision in tensile unit stress.

To summarize these comments, the experiments reported in the paper are important to structural designers and demand new thinking with respect to tension-member design. They point, however, toward many additional tests to be made before general changes in specifications are undertaken.

C. C. WINTER,[20] ASSOC. M. AM. SOC. C. E. (by letter).—The writer proposes a few problems and tests, and suggests a few changes in specifications or in the interpretation of the present ones.

Rivets.—The rivet is the fundamental element of a riveted joint. The two main variables of rivets are the grip and diameter. It is suggested that there is, or should be, some relation between small pin and rivet design. Fig. 20 shows the relation between bearing, shear, and bending based on a simple case. If the bending is only half as much as assumed in Fig. 20, it still appears to be a very important factor. The tests reported in the paper indicate that a decrease in strength can be expected as the grip increases, but the tests have a very limited variation of grip. Fatigue tests at the University of Illinois support this conclusion. German fatigue tests have developed breaks in bending.

The writer suggests that the specifications on long rivets be made more conservative; for example, "Rivets (long rivets) subjected to calculated stress and having a grip in excess of two diameters shall be increased in number at least 16% per inch of grip." Tests to isolate this problem should be relatively simple.

In Fig. 20 it appears that, for thin plates, bearing is important. These tests were made on relatively thick plates so that bearing for thin plates was not revealed. There appears considerable evidence that the allowable bearing stress can be quite high. It is probable that the rivet heads confine and assist the joint by distributing the load over a larger area.

End Distance.—The tests reported in the paper did not indicate much need for greater end distances, but these tests were for relatively thick plates. One proposed specification calls for the end distance, or edge distance, to be such as to give an area equal to the shearing area of the rivet. It appears reasonable to demand that this area be maintained between rivets to prevent tearing. Proposed: "The pitch should not be less than the end distance plus one-half the diameter of the hole."

---

[20] Res. Engr., Bridge Dept., State Div. of Highways, Sacramento, Calif.

Pitch.—In the "B" series, where full-row riveting was used, there is an indication that the maximum efficiency can be obtained when the pitch is two-thirds of the gage. This point can possibly be explained by the distribution of the Lueders lines. If the lines are at 45°, then with the pitch two-thirds of the gage, the maximum stress lines will fall between rivets and not through them. Photo-elastic studies should indicate the most efficient rivet pattern and the effect of pitch and gage on the stress in the plates.

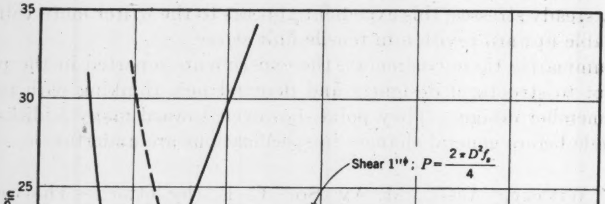

FIG. 20

Net Section.—These tests raised a large question about net section. Under the heading "Conclusions from Tests: Net Section" the following statement is made: "The experimental results bore no consistent relation to the specification requirements for determining net section."

The writer concurs that the tests do not agree with common practice and methods as shown in textbooks. However, net section, as used in the analysis of these tests and common practice, appears to be contrary to a strict interpretation of present specifications, which state that: "The net section shall be the least area which can be obtained by deducting from the gross sectional area, the area of holes cut by any straight or zigzag section across the member,

etc." If the foregoing specification permits the protection of the net section by omitting rivets in the first row, then the specifications need revision.

The grooving effect is important when full-row riveting is used. Why not take advantage of this property and use the nominal diameter of the rivet when the holes are subpunched and reamed?

* Protected net area is the first row net area as used in the tests.

† The least net area is based on the nominal diameter of the rivet, deducting one hole for each gage line.

Table 26 gives the ultimate strengths based on the nominal diameter of the rivet, one hole being deducted for each gage line, resulting in the least net section obtainable. It is found that the least net section is in fair agreement with the ultimate strengths based on mill coupons. A study of the data from

the tests by E. L. Gayhart[6] at the Bureau of Standards also gives more reasonable results when based on the least net section.

One very desirable quality of any specification is a basis upon which the ultimate strength can be predicted. The present tests do not have large riveted joints with full-row riveting and it seems desirable to perform these tests before the specifications limit the riveted joints to 75% efficiency. A set of comparable butt-welded joints might also be worthy of consideration.

Proposed: "In calculating the required net section of riveted tension members, net sections shall be used in all cases; and in deducting rivet holes, the holes shall be taken as: (*a*) $\frac{1}{16}$ in. larger than the nominal diameter of the rivet for punched holes; (*b*) the nominal diameter of the rivet for reamed or drilled holes. In determining the net width, one hole shall be deducted for each gage line."

Transverse Shear.—In regard to the findings on transverse shear on the rivets, the tests indicate many coarse square fractures with very little reduction of area. If there is transverse shear on the rivets, there must be transverse tension in the main plates and compression in the cover plates. These stresses probably contributed to the curling and buckling of the plates. The combined stress appears to have caused the square breaks. The question might be put: "What is the effect on yield, ultimate strengths and reduction of area if the lateral contraction is restricted?"

The tests seem to indicate the desirability of using full-row riveting, short compact joints, and ductile materials.

It appears that a co-ordinated program of tests should be undertaken and then a uniform specification written.

W. M. WILSON,[21] M. AM. SOC. C. E. (by letter).—To the writer, the two most important conclusions from the tests given by the authors are:

(1) The ultimate strength of a large group of driven rivets equals, approximately, the sum of the strengths of the individual rivets; and,

(2) Omitting alternate rivets from the outside row of a group of rivets, or increasing the transverse distance between the rivets, does not add greatly to the effective net section of a riveted tension member. Conclusion (1) is reassuring and highly gratifying. Conclusion (2) has been indicated by other tests, and will be the subject of the present discussion.

The specifications most used in the design of American steel bridges contain rules for determining the effective net section of riveted tension members. These rules assign considerable importance to the relation between pitch and gage if some rivets are omitted from the outside row and do not recognize the effect of the transverse spacing of the rivets upon the unit strength of the section through the rivet holes. (The outside row of rivets of a joint corresponds to the outside row of a gusset plate in the case of a riveted tension member connected to a gusset plate.) This is true although there has been a considerable quantity of experimental data available for several years, indicating that the ratio of pitch to gage for staggered rivets is a minor factor and that the transverse spacing of the rivets is a major factor affecting the strength of riveted tension members. The tests reported in this paper are of value in that they add to the accumulating evidence that present specifications are in error in both of these respects.

---

[21] Research Prof., Structural Eng., Civ. Eng. Dept., Univ. of Illinois, Urbana, Ill.

The writer has searched American literature to obtain experimental data to be used in a study of the effective net section of riveted tension members such as are used for truss members of steel bridges. With a few exceptions, the tests included in this study comply with the following requirements: (1) The width of the specimens varied from 13.5 in. to 22.5 in., inclusive; (2) the strength of the plate material as given by tests of standard control specimens was reported; (3) the specimens failed in the plate; (4) the specimens had either $\frac{7}{8}$-in. or 1-in. rivets; and, (5) the joints were generally in accord with what is accepted as good design practice. However, there were the following exceptions to the requirements: One specimen was only 10 in. wide; four specimens failed in the rivets but at a plate stress that made the tests of value. Forty-nine tests reported by four investigators complied with these requirements, except as noted, and have been used in the study (they included eight tests made at the Watertown Arsenal;[22] twenty-one tests made for the Navy;[6] four tests by Mr. C. O. Harris;[23] and, sixteen tests made at the University of California and reported in the paper being discussed). In addition to the foregoing, a number of tests of specimens 9 in. wide, made by Mr. Harris,[23] have been used in the study of the effect of the ratio of pitch to gage upon the effective net section.

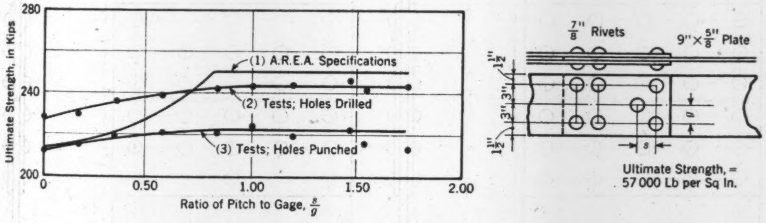

FIG. 21.—RELATION BETWEEN STAGGER OF RIVETS AND STRENGTH OF PLATE OF RIVETED JOINTS

Preliminary to the formulation of a rule for determining the effective net section of riveted tension members, the writer made one study to determine the effect of the ratio of pitch to gage on the strength of joints from which some rivets were omitted from the outer row, and he made a second study to determine the effect of the transverse distance between rivets upon the unit strength of the net section. These studies are presented herein.

The tests used in the study to determine the effect of the ratio of pitch to gage upon the strength of a joint from which rivets were omitted from the outer row include those made by Mr. Harris, some made for the U. S. Navy, and some made at the University of California. The tests made by Mr. Harris, and the details of the joint, are shown in Fig. 21. Two series of tests of riveted joints are reported: For one the holes in the plates were punched (Curve (3)), and for the other the holes were drilled (Curve (2)). A third series of tests was made by Mr. Harris for which the specimens were plates without joints, but with open holes of the same pattern as the rivets of the specimens with riveted joints. The results of these latter tests are shown by Curve (1) in Fig. 21. Tests were made in duplicate for each series and the small circles represent the average of the results of tests on duplicate specimens. The ordinates of the diagrams represent the ultimate load and the abscissas represent the ratio of the pitch to the gage. The strength of the plate material was determined by tests of standard control specimens for all of Mr. Harris' tests, and the ultimate strength for all specimens has been adjusted to a common plate strength of 57 000 lb per sq in. It is to be noted that the plates with open holes tested by Mr. Harris were stronger than the plates connected with rivets. The relation between the strength and the stagger, as computed by the American Railway Engineering Association specifications, is given in Curve (1), Fig. 21.

six specimens included three with carbon-steel plates and three with low-alloy plates. For the specimens with carbon-steel plates, the efficiency of the joints, the average of three tests in each instance, was 0.84 for Type B and 0.81 for Type D. For the specimens with low-alloy plates the corresponding efficiencies were 0.82 and 0.80. That is, changing the pitch from 0 to $\frac{2}{3}$ of the gage decreased the efficiency of the joint only about 3 per cent. (The term efficiency as used herein is the ratio of the ultimate strength as determined by test to the product of the gross area of the section and the unit strength of the control specimen.)

Two series of tests made at the University of California, and reported by the authors (Specimens No. *CCC*2 and *DCC*2, Fig. 2 and Table 5), had the rivet pattern shown in Fig. 22. The plate thickness was $\frac{3}{8}$ in. for Specimen *CCC*2 and $\frac{5}{8}$ in. for Specimen *DCC*2. The pitch, x, had values of 2 in., 3 in., 4 in., 5 in., and 6 in. for *CCC*2, and 3 in., 5 in., and 6 in. for *DCC*2. The values of the efficiency of the joints for the various values of x were as shown in Table 28. It is to be noted that varying x produced no large or consistent change in the efficiency of the joints.

The results of the three independent investigations,[6, 23] agree in one important respect: The strength of riveted joints, with some rivets omitted from the outer row, is not greatly affected by the ratio of the pitch to the gage.

In the study to determine the effect of the transverse distance between rivets on the unit strength of the net section of the plates, only two types of joints were included: (1) Joints with no rivets omitted from the outer row; and (2), joints with some rivets omitted from the outer row but only those which had a pitch equal to, or greater than, the gage. They included tests from all four investigations. The relation between the ratio, $\frac{\text{Strength of net section}}{\text{Strength of control specimen}}$, and the transverse distance between rivets is shown by the small circles of Fig. 23.

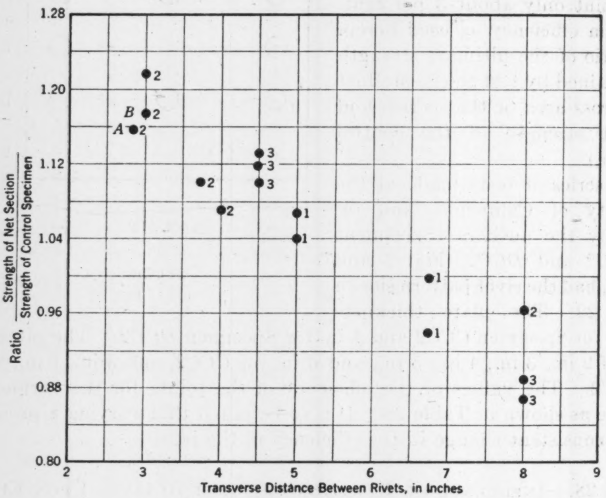

FIG. 23

The numeral adjacent to each circle indicates the number of tests of identical specimens averaged. The study includes twenty-eight tests and a variation in gage from $2\frac{7}{8}$ in. to 8 in. The points marked *A* and *B* are for specimens that failed in the rivets. It is apparent from Fig. 23 that the unit strength of the net section of a riveted tension member is greatly affected by the transverse distance between the rivets.

In view of the discussion contained in the previous paragraphs, it appears that any rule for determining the effective net section of a riveted tension member should take into consideration the net section through the outer row of rivets and also the transverse distance between rivets. Furthermore, it would appear unnecessary to consider the effect of minor variations in the ratio of the pitch to the gage for joints with rivets omitted from the outer row. With these ideas in mind the following empirical rule for determining the effective net section has been developed.

The effective net width (W_n) of a riveted tension member is given by the equation

$$W_n = (W_g - N\,D)\left(1 + \frac{D}{G}\right)0.85 \ldots\ldots\ldots\ldots\ldots (4)$$

in which W_g = gross width of the member; D = nominal diameter of the rivet plus $\frac{1}{8}$ in.; N = number of rivet holes to be deducted; and, G = transverse distance between rivets, or two times the edge distance, whichever is the greater.

If rivets are omitted from the outer row, N and G shall be determined by the rivets in the outer row provided the pitch equals or exceeds 0.80 of the gage; otherwise the intervening rivets in the second row and all of the rivets in the outer row will be considered in determining N and G.

Equation (4) is composed of two parts: One is the actual net width, and the other is a factor to compensate for the effect of the transverse distance between rivets upon the ratio, $\frac{\text{Unit strength of net section}}{\text{Unit strength of control specimen}}$. Values of this latter factor for various values of $\frac{G}{D}$ are shown in Fig. 24.

The proposed rule for determining the effective net section of riveted tension members has been applied to the forty-nine tests of the four investigations cited[6, 22, 23] at the beginning of this discussion and the results are presented in Table 29. In this table, Column (5) contains values of G determined in the manner described in the preceding paragraphs. Column (6) gives the efficiency of the joint, the efficiency being the ultimate load, as determined by test, divided by the product of the gross area and the unit strength of the control specimen. Column (7) gives the effective net section as given by test, this being the ultimate strength, as given by the test, divided by the unit strength of the control specimen. Columns (8) and (9) give the computed values of the net section, the former being by the A. R. E. A. specifications for railway bridges and the latter by the proposed specifications. Columns (10) and (11) give the ratios of the computed to the test values of the net section, the former being for the A. R. E. A. specifications and the latter for the proposed specifications. A value greater than unity indicates that the computed value exceeds the value determined by test. A perusal of the values in Columns (10) and (11) reveals the agreement between the computed values and the values determined from tests.

It is of interest to note that the largest value of R given in Column (10) is 1.149, in Line 21, and the smallest value is 0.820, in Line 15, indicating that the A. R. E. A. specifications gave a value for the net section 15% too great for one specimen and 18% too small for another specimen. The largest value of R_1 given in Column (11) is 1.061, in Line 21, and the smallest value is 0.928, in Line 15, indicating that the maximum difference between the two values, one given by the proposed specifications and the other by the tests, is only 7 per cent. It is to be noted further that, in general, the proposed specifications give a value more nearly equal to the value given by tests than do the A. R. E. A. specifications. Moreover, the proposed specifications penalize the bad practice of using an extremely large transverse spacing of the rivets and large edge distances in the outside row of rivets, expedients which, according to A. R. E. A. specifications, result in a high efficiency but which, according to tests, resulted in little, if any, increase in efficiency.

In the proposed rule, *G* is defined as the transverse spacing, or two times the edge distance, whichever is the greater. If the transverse spacing varies, the widest space, or two times the edge distance, is to be used.

If all of the transverse spaces are equal and if the edge distance is one-half of the transverse spacing, the net section can be expressed as a fraction of the gross area and the value of the fraction depends only upon the ratio of *G* to *D*. The relation between the ratio $\frac{\text{Effective net section}}{\text{Gross section}}$ and the ratio $\frac{G}{D}$ is given in Fig. 24(*b*). It is apparent from this diagram that the efficiency of a joint does not increase appreciably with an increase in the transverse spacing beyond a value of $G = 6\ D$.

The authors have drawn the conclusion that the efficiency of a riveted tension member does not greatly exceed 75%, irrespective of the transverse spacing of the rivets. If a different rivet pattern had been used for the joints with a large transverse spacing, it is believed that a different conclusion would have resulted. All of the specimens with a large transverse spacing that were tested by the authors had no rivets at the ends of the outside row, and the edge distance was abnormally large for the weakest section of the main plate. Thus, for Specimens *CCC*2 and *DCC*2, shown in Fig. 22, the edge distance for the outside row of rivets is 6.5 in. Geometrically, this is equivalent to a transverse rivet spacing of 13 in., whereas, for the interior rivets of the outside row, the spacing is only 8 in. Moreover, the authors report in another part of the paper that, beyond the yield point, the unit longitudinal strain in a wide plate is greater over the middle than it is at the edges. This being true, the harmful effect of placing the rivets on the weak section near the mid-width accentuates the harmful effects of a wide edge distance. This statement is supported by the tests reported in Table 29, which are discussed in the following paragraphs.

The only specimens for which the value of the effective net section determined by the proposed specification exceeds the value given by the tests is for those tests reported in Lines 5, 6, 17, 21, 22, 23, and 24, Table 29.

The details of the specimen used in the test reported in Line 5 are shown in Table 30 (Specimen 8510). The edge distance is 3⅞ in. The proposed specifications give a value for the effective net section 0.70% greater than the value given by the test.

The details of the specimen used in the test reported in Line 6 are also given in Table 30 (Specimen 9375). The edge distance is 5 in. The proposed specifications give a value for the effective net section 1.2% greater than the value given by the tests.

The specimens used in the tests reported in Line 17, Table 29, had a close spacing and a small edge distance; but the fact that the computed value of the effective net section exceeded by 1.0% the value given by the tests is accounted for by the fact that the failure of the specimens was due to the shearing of the rivets and not by a failure of the plate. All other specimens for which the computed value of the effective net section exceeded the test value had the same rivet pattern as the specimens of Fig. 22. That is, the few instances in which the computed value of the effective net section exceeded the test value can be accounted for by the fact that the edge distance was large for the outer row of rivets.

The specimens shown in Table 31 have practically the same transverse spacing of rivets, but Specimens *DCC*2 have two rivets near the middle of the outer row, whereas Specimens of Type *F* have one rivet at the center and one at each end of the outer row.[6] The computed and test values of the efficiency are equal to each other and equal to 0.80 for Specimens *DCC*2, whereas, for Specimens of Type *F*, the computed efficiency is 0.80 and the value determined from the test is 0.85, the values being the averages from three tests in each instance. That is, although the computed value of the effective net section for Specimens *DCC*2 is reduced because of the large edge distance, the computed value is still greater, relative to the test value for these specimens, than it is for the specimens of Type *F*, which have a small edge distance.

The fact should be noted, however, that the specimens used for the tests reported in Lines 1, 2, 3, and 4, Table 31, had edge distances equal to one-half the transverse spacing and yet they developed an effective net width somewhat greater than the computed value.

4	Effective net section, by test, in square inches	8.32	8.41
5	Net section by American Railway Engineering Association specifications	8.93	9.33

As a result of the analysis of the data contained in Table 29, the following rules for the design of riveted tension members are submitted for the consideration of the profession:

Rule 1. Effective net width = $(W_g - N\,D)\left(1 + \frac{D}{G}\right) 0.85.$

Rule 2. The edge distance shall not exceed 2.5 *D* for the outer row of rivets.

In the foregoing equation (Rule 1): W_g = gross width of the member; N = number of rivet holes to be deducted; D = nominal diameter of the rivets plus $\frac{1}{8}$ in.; and G = transverse distance between rivets or two times the edge distance, whichever is the greater.

For joints with rivets omitted from the outer row, only rivets in the outer row are to be considered in determining *N* and *G*, provided the pitch equals or exceeds 0.80 of the gage; otherwise all rivets in the outer row and the intervening rivets in the second row should be considered in determining *N* and *G*.

In the preceding discussion it has been assumed that the weakest section of a riveted tension member is through the outside row of rivets of the gusset plate at the ends of the member. The writer knows of no published reports of tests of riveted tension members with stitch rivets, but the tests of plates with holes by Mr. Harris, reported in Fig. 21, indicate that an open hole does not weaken a plate as much as a rivet transmitting stress. It is not reasonable to suppose that a stitch rivet weakens a plate more than an open hole. It would seem reasonable, therefore, that the foregoing rules of design, which are applicable where the rivets transmit stress, give conservative results where the rivets do not transmit stress but only serve as stitch rivets. The only probable exception to this statement is where stitch rivets are used to connect two parallel pieces of steel having widely differing stress-strain diagrams. Under this latter condition one piece, because of its lower ductility, might break before the other had been stressed to its ultimate strength. This condition is not likely to occur in a member fabricated of a carbon steel of structural grade because the part of the stress-strain diagram near the maximum stress is nearly horizontal for a considerable length. However, the behavior, under similar conditions, of a member fabricated from parallel pieces made of a steel which is not uniform in its physical properties is somewhat uncertain.

J. M. GARRELTS,[24] ASSOC. M. AM. SOC. C. E. (by letter).—The engineering profession is indebted to the engineers of the San Francisco-Oakland Bay Bridge who provided for this important series of tests, and to those who were responsible for making the tests and analyzing the results. As has been advocated by some consulting engineers, a series of well-planned tests, made in connection with the important structures which are built, would soon yield valuable information concerning the behavior of structures.

The fact that under different stresses "the plates in a riveted joint tend to elongate by unequal increments" is important and should be used in the analysis of many structural problems as well as in that of the riveted joint. As allowable unit stresses increase, structural design must be placed on a more scientific basis. The structural designer must be aware of the many indeterminate factors that affect the action of a structure and must have some knowledge of the influence of those factors.

In order to determine the effective net section and the effect of end pitch, additional data are needed concerning the behavior of plates with open holes under stress. The lines of fracture for the specimens shown in Figs. 6 and 7 all appear to originate in the regions of high stress concentration. When a condition of plastic yielding is reached, a redistribution of stress takes place, but initial fracture may occur in the region where yielding first occurs. If stress concentration at the edges of a hole has any bearing on the initial fracture, it is quite probable that the present ideas concerning net section need to be revised. The writer is of the opinion that, by additional study and tests, a rational analysis may result. In the meantime, the authors' recommendations appear to represent a reasonable procedure.

In view of the uncertain action of the riveted joint in Stage II, the authors' recommendations for assuming equal shear per rivet seem fully justified and no additional refinement is likely to result from further tests.

A. E. RICHARD DE JONGE,[25] M. AM. SOC. C. E. (by letter).—The tests described in this paper are perhaps the most elaborate tension tests conducted to date on large-size structural riveted joints. A variety of specimens was tested, in which several characteristics were changed systematically. The questions that were to be answered by these tests are clearly stated under the eight items at the end of the "Introduction", and the answers are given in "Conclusions from the Tests".

[24] Associate Prof., Civ. Eng., Columbia Univ., New York, N. Y.

[25] Adjunct Prof., Polytechnic Inst. of Brooklyn, Brooklyn, N. Y.

After reading the lengthy report, the writer who has made an extensive study of the world's literature on riveted joints[26], would like to take stock of what has really been accomplished by these very expensive tests. In so doing, he is not going to discuss the eight items previously mentioned, but will rather deal with those factors that have an influence on the strength of riveted joints, in so far as they have been treated by the authors.

(*1*) *Strength of a Riveted Joint.*—The meaning of the term "strength of a riveted joint" should be revised so as to be in accordance with actual facts. In the past, too much emphasis has been placed on the ultimate strength of a riveted joint. With the modern means of investigation, there is no reason why the method introduced more than one hundred years ago by Sir William Fairbairn[27] should still be adhered to to-day. In service, no actual joint is ever stressed anywhere near the breaking point. Therefore, it matters little whether the joint, if stressed to the breaking point, fails in the rivets or in the plates; in both cases the joint becomes useless. In fact, if the rivets would fail before the plates become distorted to any great extent, it would be possible to re-rivet the joint, thereby making it again serviceable. This is impossible, however, when the joint fails in the plates.

Consequently, it is of far greater importance to determine what happens in a riveted joint up to the maximum working load than to pull the joint apart—that is, subject it to conditions to which, ordinarily, it would never be subjected in practice. The only reason for the ultimate strength test is to provide data for a convenient, although wholly inadequate, method of calculation which, by the introduction of a suitable factor of safety, assures sufficient safety at the maximum working load that the joint is called upon to sustain. Substituting for this "factor of ignorance" a thorough knowledge of the phenomena that occur in the joint, from the moment a load is applied to it until this load has reached the maximum value allowable under ordinary working conditions, would lead to a rational method of calculation which, at present, is sadly lacking. The maximum working load should remain sufficiently far below the yield strength of the riveted joint rather than below the ultimate strength. The yield strength would then form the true strength limit for the joint, which can ordinarily be utilized. However, since the authors have followed a long-established precedent[27] in subjecting riveted joints to breaking loads, a discussion of the various factors that control the strength of a joint, up to the point of fracture, will be necessary.

(*2*) *Tests of Solid Plates.*—The authors have subjected two solid plates each of Series C and D to tension tests. They were of carbon steel, and had a width of 21 in. and a gage length of 24 in., two being $\frac{3}{8}$ in. thick and the other two, $\frac{5}{8}$ in. thick. Marked yielding occurred in the $\frac{3}{8}$-in. plates at 37.9 kips per sq in., and in the $\frac{5}{8}$-in. plates at 34.8 kips per sq in. The $\frac{3}{8}$-in. and $\frac{5}{8}$-in. plates failed, respectively, at strengths of 92% and 94% of that of the test coupons. The ratios of lateral set to longitudinal set, at failure, were 0.38 for the $\frac{3}{8}$-in. plates and 0.40 for the ⅝-in. plates. Poisson's ratio was found to be 0.28 for both plate thicknesses. The plates failed at mid-length. In three specimens, a short transverse crack started in the middle of the plate, whereas in the fourth the first crack developed at one edge. The authors measured the longitudinal strains at 30 kips per sq in. and found them to be uniform—that is, the strains were the same at the center as at the edges. In one ⅜-in. plate, the strains were measured at 35 kips per sq in. (that is, very close to the yield point) and were found to be 11% greater in the middle than at the edges.

[27] "Experimental Inquiry into the Strength of Iron with Respect to Its Application as a Substitute for Wood in Shipbuilding," by William Fairbairn, British Association for the Advancement of Science, Tenth Meeting, Glasgow, Scotland, Reports 1840, Vol. 1840, pp. 201–202; see also *Philosophical Transactions*, Royal Soc. of London, Vol. 140, 1850, pp. 677–725.

The authors attribute the tendency for the failure of the plates to start in the middle to the unequal distribution of longitudinal strains. To the writer, this seems to be correct, but it requires amplification to explain this behavior.

As long as the cross-contraction is approximately the same over the gage length, the strains are the same everywhere in the plate. A network of small squares scratched into the surface of the plate at the beginning would simply be changed into a network of rectangles. However, shortly before yielding becomes general, a slight necking occurs at the edges of the plate, usually at mid-length. This is an indication for a redistribution of the material. The thicker the plate, the easier this redistribution will proceed—that is, the more marked will the necking become. In the region of necking, the small squares are distorted into a kind of trapezoid with curved sides; but the orthogonal system of tension and compression lines that coincides with the sides of the original squares must remain orthogonal. The greatest lengthening of the tension sides of these squares, therefore, takes place at the center of the plate in the region where necking at the edges occurs. This appears to be the reason why the first crack must start in the middle of the plate instead of at the edges. As the redistribution of the material takes place easier in thick than in thin plates, it is to be expected that the final set must be greater in thick than in thin plates. This is precisely what was observed. Why failure started at the edge, in one case, cannot be determined without further knowledge of the fracture. It seems likely that, due to a slight notch effect at the edge, the crack started from this notch.

Because the redistribution of the material is more difficult in thin plates than in thick plates and a round bar, and because the elongation of the ⅜-in. plates is less than that of the ⅝-in. plates, as observed by the authors, the ultimate strength exhibited by the ⅜-in. plates did not reach that of the ⅝-in. plates and was lower than that of the test coupons (92%), whereas the ultimate strength shown by the ⅝-in. plates was somewhat higher, but still below that of the test coupons (94%). Thus, the foregoing explanation describes all the observed facts accurately. Furthermore, if a ⅜-in. plate is bent into the shape of a cylinder (that is, if it is formed into a tube of ⅜-in. wall thickness, with a lateral surface equal to the width of the original ⅜-in. plate), and if it is then pulled apart, it will most likely be found that the strength approaches much closer that of the test coupons, because the entire wall of the tube can now contract together with the latter (necking) at right angles to the surface. If the plate should become a bar, the thickness of which is equal to its width, and if it were possible to tear it apart, it would probably be found that its strength would approach that of the test coupon very closely. To the writer, these appear to be the reasons underlying the strange behavior of wide plates. As the tests by the authors have revealed these facts, it can be said that these experiments have served a useful purpose.

(*3*) *Effective Net Section and Grooving Effect.*—Of effective net section, grooving effect, rivet pattern, omission of rivets in the outer rows, pitch, and gage-line distances—all of which factors are intimately interconnected—let the first two be discussed at this point.

The authors claim that "an outstanding finding of these tests is that the strength of the plates in a riveted joint is not directly proportional to the area of the net section as commonly assumed in practice". Theoretical and experimental studies on the net section have previously been conducted by C. R. Young[28], M. Am. Soc. C. E., and by Professor Young and W. C. Dunbar[29], in which it was found that the net section, assumed to be stressed uniformly, is not thus stressed, and is not a simple function of the rivet-hole arrangement. T. R. Loudon[30] also found, by using photo-elastic analysis, that there are high stress concentrations near the rivet holes, and that the stress is, by no means, distributed uniformly over the section remaining between the rivet holes. Therefore, the authors can scarcely claim priority for their finding.

Probably the entire question of net section would long since have assumed a different aspect if the stress distribution, as found by Prof. E. G. Coker[31] and by Professor Loudon[30], had been considered more carefully; for a phenomenon, termed the "grooving effect," occurs in which the material in the vicinity of the rivet absorbs a greater part of the stresses than the material farther away so that the material between two closely spaced rivet holes exhibits an apparently greater strength. This phenomenon was first stated definitely by Daniel Adamson[32], in 1878, although, previously in 1872, Walter R. Browne[33] had shown that the stress distribution in the remaining cross-section is not uniform, the stress being greater near the hole. According to William Hovgaard[34], the material of mild steel plates, $\frac{3}{8}$ in. to $\frac{3}{4}$ in. thick, absorbs, between two rivets spaced at a gage of three times the diameter (3 *D*), a 10% higher stress than does the solid plate ahead of the rivets. This amount drops to 5% if the gage distance between rivets is four times the diameter (4 *D*). The grooving effect is of the utmost importance with regard to the rivet arrangement or rivet pattern, as will be shown subsequently.

(*4*) *Rivet Pattern, Omission of Rivets in the First Row, Pitch, and Gage-Line Distances.*—Only a few, and scarcely representative, rivet patterns were investigated by the authors. Long ago it has been shown that the omission of rivets in the first row, for the purpose of increasing the strength of riveted joints, is a fallacy[35] (Meldahl showed that, in the case of a saw-tooth like doubling plate, the maximum stress occurs slightly ahead of the ends of the saw-teeth, and that fracture actually started at those points); it is based on the misconception that the stress between the rivets of the first row is uniformly distributed (assumption by J. W. Schwedler[36]). Even as far back as 1860, Sir William Fairbairn[37] recommended, where greatest strength combined with lightest weight is desired in bridge girders, the use of chain riveting or placing the rivets in the various lines, one behind the other, instead of "in zigzag" as was customary at that time. (The writer, here, uses the term "rivets in line" for rivets placed longitudinally one after the other, and the term "row" for rivets spaced side by side transversely to the direction of the acting force.) The same recommendation was made again by Commander Gayhart, in 1926, on the basis of his very elaborate tests[6]. Gayhart showed conclusively that chain riveting (placing the rivets in line one after the other and using like lines, evenly spaced, side by side) is stronger than riveting in which, alternately, one or more rivets in the first row are omitted. Since this was well known at the time these tests were planned, the writer would have expected that the joints for these tests would have been laid out with due regard for this fact. The only specimens that approach fairly closely the chain riveting recommended by Fairbairn and Gayhart are those of Series B. However, due to the omission of two rivets in one of the inner rows of each specimen of this series, these specimens cannot be regarded as good examples of joints designed for greatest strength. Nevertheless, the tests proved that these joints had a better efficiency than other joints—for instance, those of Series A.

[34] "Structural Design of Warships," by William Hovgaard, E. and F. N. Spon, Ltd., Spon and Chamberlain, London, 1915, p. 121.

The reasons why full-row rivet spacing in the first row shows a greater strength are: (1) The grooving effect (the capacity of the material between narrowly spaced rivets to absorb greater stresses than the material between widely spaced rivets); and (2) the fact that the stress distribution in the case of narrow, even rivet spacing is far more uniform than that in the case of widely spaced rivets, as has been shown, for example, by Coker who used photo-elastic analysis[31]. Thus, by spacing the rivets in the outer rows evenly and closely, dangerous stress concentrations are avoided at these rivets.

Next, rivet pitch, particularly between the first two rows in the case where the rivets in these are spaced in zigzag, has been investigated by the authors, in Series C and D. In all cases, the fracture passed through the two outermost rivets and showed almost always a tendency to follow shear lines inclined at about 45 degrees. This tendency was greater in the ⅝-in. plates than in the ⅜-in. plates. Where the second row of rivets was near enough (Specimens CCC2–2 and DCC2–3), the fracture passed in zigzag through first and second row rivets[38]. An interesting feature is that, at yield load, Specimens CCC2–2 and CCC2–4 showed about the same efficiencies, whereas the specimens with the intermediate pitch of 3 in. (CCC2–3) exhibited considerably lower efficiencies. At ultimate loads, however, the efficiencies vary as shown in Table 7. In that case, the maximum efficiency for both ⅜-in. and ⅝-in. plates is reached for an end-row pitch of 4 in. For smaller, as well as for greater, pitches, the efficiency was lower.

The rivet pitch throughout the joint was the only variable that was changed in the specimens of Series B. The gage distance was rather large (7.5 in.), and thus, in the light of what has been said about the stress distribution, the joints cannot be regarded as being representative of best or even ordinary practice. Nevertheless, the results are of interest in so far as they show that joints with 4.5-in. pitch throughout were stronger than either those with 3-in., or those with 6-in., pitch (see Table 15). It is to be regretted that no attempt was made to vary the gage-line distances as this would have revealed the optimum condition of pitch relative to gage distance. It is obvious that, when the gage-line distance is too great, stress concentrations at the outer row of rivets will appear so that the stress distribution will become uneven, resulting in reduced strength.

The effect of the change in gage distance, or of the number of holes in a given section, may be judged, to a certain extent, from Specimens CCC5 and DCC7. It should be kept in mind, however, that the former consisted of ⅜-in. plates, whereas the latter were composed of ⅝-in. plates. As may be expected from what has been said about the grooving effect, Specimens DCC7 with the narrow-gage distances of 3 in. sustained a greater load (more than 76.2 kips per sq in. of net section) than did Specimens CCC5 with the wider gage distances of 4 in. (70.9 kips per sq in.). The grooving effect of the narrow-gage distances proved sufficient to prevent failure in the plates in spite of the higher stress in the net section, the joints, in this case, failing in the rivets.

(*5*) *Bending in Lap Joints.*—In its essentials, the foregoing discussion, under Items (3) and (4), applies equally to lap joints and butt joints. The high bending stresses that usually occur in lap joints, particularly in short ones, were eliminated by the authors to a certain extent by the use of a "bending frame". While, thus, the values indicated in Table 5 are intended to represent data purely in tension without bending, it must be kept in mind that bending is always present in actual lap joints. The bending stresses that occur should be placed on the debit side in such joints. The values given by the authors, therefore, have only a theoretical interest and should be used with caution wherever bending stresses are present at the ends of the lap, particularly since the bending frame tended to increase the friction between the plates.

(*6*) *Efficiency of Lap Joints.*—In Table 5, the authors have given the efficiencies for lap joints that failed in the plates, as well as for those that failed in the rivets. The efficiencies of joints of Series C and D which failed in the plates vary from 72.8% to 78.8%, the mean being approximately 75 per cent. Considering the different types of rivet patterns, the different lengths of the laps, the different pitches and gage-line distances, and the different kinds of steel, it seems remarkable that the differences in the efficiencies were not very much greater. However, it should be emphasized again, that, for a joint used in actual construction, the ultimate efficiencies mean little; it is rather the efficiency up to, or at, the yield strength of the joint that is of importance and should so be considered by the designer.

(7) *Rivet Data.*—

(a) Driving Temperatures.—The strength of a riveted joint depends, to a large extent, on the clamping effect of the rivets, and this, in turn, on the temperatures at which the rivets were driven. Two temperatures are of importance—the one at which driving starts and the one at which it ends. The data given by the authors are extremely scanty. No definite temperatures are given. As to the temperature at which driving started, the authors give the range and average in a general way: For carbon-steel rivets from 1 400° F to 1 800° F, with an average of 1 570° F, and for manganese-steel rivets from 1 400° F to 1 900° F, with an average of 1 680° F. The far more important end temperatures at which the ram of the hydraulic riveter completes the forming of the snaphead, and that at which it leaves the rivet, are not stated; and yet, these have a deciding influence on the strength of the joint. Furthermore, no mention has been made as to how these temperatures were measured. It is hoped that the authors will give further information as to these important factors in their closing discussion.

An extensive investigation of the most suitable rivet temperatures at the beginning and end of driving was published by Yasuchi Taji[39], in 1914. Taji recommended the use of the lowest possible temperatures, with riveting done as quickly as possible. Although he used a wide range of temperatures at the start of driving the rivets, his general average, in hydraulic riveting, is 817° C (about 1 503° F). Although this average value is lower than that used by the authors, it is well within the range used by them. For the lower end temperature, Taji gives, as the best value, 650° C (about 1 200° F), and this is in remarkably good agreement with the optimum end temperatures given in 1886 by A. Considère[40], in France, who recommended an end temperature of from 600° to 700° C (about 1 100° to 1 300° F). If one considers that the average temperature used by Taji was almost 70° F lower than that used by the authors, it is questionable whether the end temperatures in the authors' case were close to the best end temperature recommended by Taji.

That better strength values may be obtained by using lower temperatures is borne out by some of the authors' specimens of Series A (manganese-steel rivets and double-plate joints). Without giving the actual temperature at the start of driving, the authors state that it was about 100° F less than in the other cases of this series; yet, the strength of these joints was found to be well above that of the other joints, and the rivets had a greater hardness and finer grain structure. Other investigators, too, have obtained better results at lower initial temperatures—for instance, Professors Young and Dunbar[41], whose grand average was 1 384° F. It is to be deplored that the authors did not follow up this clue by experimenting with somewhat lower temperatures, using joints of a definite type, but with rivets driven at different initial and final temperatures.

(b) Rivet Strength.—As stated under Item (7), the strength of a rivet and, thus, also of the joint depends on the temperatures at the beginning and end of driving. The important question, however, is what the actual strength of a driven rivet is as compared with that of the undriven rivet and the stock from which the rivet was made. The authors have given yield strength and ultimate tensile strength for the rivet-rod stock, and the shear strength for undriven rivets, but no actual shear strengths of driven rivets except the mean shear strengths as computed from the tests of the joints. In Tables 9, 10, 12, 13, 14, 15, 17, and 19, average shear stresses are given which are computed for effective rivet yield, yield load, and ultimate load. For the latter, the authors have stated that it was found "by dividing the total load by the total shearing area of rivets, based on the nominal diameter of the rivet". However, nothing has been mentioned about how the other two values were obtained. At the "effective rivet yield" and yield load, the shear is certainly not distributed uniformly over all the rivets of the joint. Therefore, it is not clear how the shear values in these cases were obtained. At ultimate loads, however, it seems likely that the shear is more or less uniformly distributed.

Furthermore, it should be kept in mind that the rivet-rod stock and the rivet produced from it by a heating process, if subjected to shear, are stressed more or less biaxially, whereas the driven rivet, which, due to contraction by cooling, is under tension, is stressed triaxially if subjected to additional shear. This explains the differences in the shear values for rivet-rod stock, undriven rivets, and driven rivets.

For the foregoing reasons, the values tabulated by the authors cannot be regarded as absolute values, but only as relative values for the purpose of making some kind of a comparison possible. Caution is urged, therefore, in using these values.

(c) Single Shear vs. Double Shear.—Under this heading, the authors mention in their "Conclusions from the Tests" that a value as low as 0.80 is indicated for the ratio of double shear per shearing surface to that of single shear. The authors state that this value agrees with findings from their pilot tests. It is not quite clear how this value was derived, because if one compares, for example, the ultimate shear values per shearing surface for Specimens FSCA and ASC18 (namely 41.6 and 54.8 kips per sq in., respectively) their ratio is 0.76, which is a still lower value and much lower than that found by other investigators. E. S. Fitzsimmons[42], for example, obtained, for carbon-steel rivets in double shear (per two shearing surfaces), 84 kips per sq in., and for like rivets in single shear, 49 kips per sq in., from which the value of the ratio of double shear per single surface to single shear follows as 0.857. Other investigators have found this ratio to be approximately 0.9. As the aforementioned specimens vary considerably in rivet pattern, rivet diameter, and width and thickness of plates, this comparison is, probably, not a fair one. It would have been of great value if the authors had conducted tests with otherwise similar specimens, in single and in double shear, with one and more rivets.

---

[42] "The Shearing Strength of Rivets," by E. S. Fitzsimmons, *Iron Age*, Vol. 75, 1905, p. 2058.

In that case, reliance could be placed on an average value obtained thereby; but this, certainly, cannot be said about the value of 0.80 given by the authors. It should be mentioned, however, that, in their recommendations, the authors have used the value of 0.9, which they, too, probably consider as the most likely one.

(8) *Influence of Plate and Rivet Material.*—Two types of rivet steels were used in these tests—a carbon steel and a manganese steel. The tensile strength of the rivet-rod stock is given by the authors, for ⅞-in. and 1-in. carbon-steel rods, and for the 1-in manganese-steel rod, as 58, 57.2, and 81 kips per sq in., respectively. The great loss in tensile strength of the annealed manganese steel, to 74.7 kips per sq in., should be noted. It is to be regretted that the data on these steels are very fragmentary. In the first place, the shearing strengths in single and double shear of the rivet-rod stock, as stated, are not given; neither are the moduli of elasticity and shear, nor the relationship between elongation and stress. For "non-driven rivets", the shearing strength in double shear (probably per single shearing surface) is given for 1-in. carbon-steel and 1-in. manganese-steel rivets, but the shearing strength in single shear is not stated. If the maximum shearing strength (in single shear) is assumed to be 0.8 of the ultimate tensile strength of the rivet-rod stock (a factor which, usually, is not far from the actual), the shearing strength in single shear, for the carbon-steel and manganese-steel 1-in. rivets, would be obtained as about 45.8 and 64.8 kips per sq in., respectively. The ratios of double shear per single shearing surface to single shear would then follow as $\frac{42.1}{45.8} = 0.92$ and $\frac{54.5}{64.8} = 0.84$, respectively—values which are more in accord with those of other investigators as stated previously herein. In double shear, the undriven manganese-steel rivets were a little more than 29% stronger than the carbon-steel rivets. If the ultimate shearing strength of Specimens ACC–18 and ACM–12 is compared, it is found that the mean in the case of the former was 55.7 and in that of the latter 75.9 kips per sq in. Hence, in these joints, the manganese-steel rivets proved to be about 36% stronger than the carbon-steel rivets. However, one must not lose sight of the fact that the joint with carbon-steel rivets was longer than that with manganese-steel rivets, the plates, in both cases, being of carbon steel.

As regards the three kinds of steel used in the various joints, the authors have failed to state the exact ultimate strength of the plates used in each joint. Likewise, the moduli of elasticity and shear are not given and neither are the stress-strain relations. Thus, the checking of the elastic properties of the joints is made impossible. Unless the authors supply these values in their closing remarks, this entire set of data is useless from the point of view of developing a rational method of calculating riveted joints. The statement that the effect of the plate steel in joints which failed in the rivets was neither large nor consistent, although the decrease in shearing strength of the rivets with length was somewhat more marked in the case of the carbon-steel plates than with less ductile steels, should be questioned. One would have expected that the harder silicon steel would exert a stronger cutting action, a fact which is actually borne out by a comparison of Specimens ASC–18 and ACC–18. In the former, the average ultimate shearing value was 54.8 kips per sq in., whereas in the latter, it was 55.7 kips per sq in., thus showing that the shearing strength of the rivets in the case of silicon-steel plates is slightly less than that in the case of carbon-steel plates. This holds even for plates with manganese-steel rivets, for, in comparing the respective shearing values for Specimens ASM-12 and ACM-12 (namely, 72.4 and 75.9 kips per sq in.), the shearing strength of the rivets in these joints with silicon-steel plates is found to be somewhat lower than that of the joints with carbon plates. In general, the combination of nickel-steel plates and manganese-steel rivets seems to be better than that of silicon-steel plates and manganese-steel rivets. In order to arrive at a decision as to which combination is the best under a given set of conditions, further experiments appear to be necessary which should be made with the strongest joints that can be designed, keeping in mind the facts dealt with in this discussion.

(*9*) *Effect of Length of Joints and Premature Rivet Failure.*—In general, the authors have described, correctly, the effect of length of a joint. As is well known from former tests and theoretical considerations, the strength of a riveted joint decreases with its length[43]. It stands to reason that the longer the joint, the greater will be the end slip and the more likely will the rivets in the end rows shear off prematurely—that is, before ultimate failure of the joint. The more ductile the steel of the plates, the greater will be the elongation and slip, and the more readily will the end rivets be sheared off. Therefore, this tendency is greatest in carbon-steel plates, and less in silicon-steel and nickel-steel plates. For the latter, in combination with manganese-steel rivets, the authors did not observe any such tendency.

A fact not discussed by the authors is that, when the end rivets failed, the joint with the remaining rivets still proved strong enough to withstand the full load. As the outer rivets failed almost consistently, it is obvious that they carried a greater load than the others. On the other hand, the next row, or the over-next row when the rivets in the two or three outer rows failed, made the plates (on account of the closer rivet spacing in the subsequent rows) relatively stronger due to the grooving effect, and the stressing of the remaining rivets became more uniform due to the more uniform stressing of the plates. Thus, one cannot escape the conclusion that the rivets in the outer row (or rows) were unnecessary for developing the maximum strength exhibited by the joint. This is a further proof for the fact that, even at ultimate loads, joints with closer rivet spacing in the outer rows are stronger both in the plates and in the rivets. That the transverse contraction of the plates increases the relative displacement of the rivet holes in adjoining plates is obvious. However, the authors' statement that "excessive detrusion, rather than stress, caused such failures," cannot be accepted by the writer as the actual stress always increases until failure occurs. Unfortunately, engineers accept the usual stress-strain curves, in which the curve, after reaching a maximum, drops again, without being conscious of the fact that these curves are, for convenience, referred to the original cross-section of the test bar instead of (as they should be) to the smallest cross-section in the region of necking. If the curves were thus replotted, it would be found that they would rise continuously up to the point where fracture finally occurs. Therefore, the statement that these outer rivets failed by overstressing is fully justified, the so-called theory of limit design to the contrary notwithstanding[44].

[43] "Inanspruchnahme der Anschlussnieten elastischer Stäbe," by Ivan Arnovļević, *Zeitschrift für Architektur und Ingenieurwesen*, Vol. 14, 1909, pp. 89–106.

(*10*) *Butt and Shingle Joints.*—The efficiencies of the joints of Series F showed that the short butt joints had the highest efficiencies—75.2 per cent. Comparing the double-plate butt joints with the double-plate shingle joints (the respective efficiencies of which are 73.0% and 72.1%), it will be seen that the efficiency of the butt joints is slightly higher, as it should be according to theory[43, 45]. As is to be expected, the longer joints showed the lower efficiencies. The authors' statement that the advantage of the lighter shingle and half-shingle splices, compared with the heavier butt splices, is offset by greater difficulty in field erection should be noted. The triple-plate, half-shingle joint (Fig. 16(*b*)) does not seem to have been designed correctly, for it fractured, as one would expect, near the unsymmetrically arranged butt of the center plate. The authors state that the outer splice plates in the triple-plate butt joint (Fig. 15) were shorter than had been intended, and the twenty-seven rivets that passed through inner and outer splice plates transferred 61% of the load from the main plate to the splice plates, whereas the thirty rivets that passed through only the inner splice plates transferred but 39% of the load. The question should, here, be raised as to what this load was—whether it was the ultimate load or some other load—as the load distribution varies with the load. The authors have failed to state this clearly. In explanation of the somewhat unexpected load distribution in these joints, it may be said that the longer rivets were probably under a higher tension than the shorter ones, and that, for this reason, they exerted a greater clamping pressure on the plates. The friction, which, up to the time of fracture, undoubtedly played an important part, was probably the cause of this rather strange distribution of load. The same explanation holds also for the double-plate butt joints, although to a lesser extent.

The authors have undertaken extensive strain measurements on specimens of this Series F. It is to be regretted very much that the results of these measurements were not presented in tabulated form to enable the investigator to check the results by calculation. Apparently, what the authors have done (although they have not stated this clearly) is to compute the stresses in the net section of the various plates for different loads (7.5, 15, 22.5, and 30 kips per sq in., or 15 and 30 kips per sq in.) and then to average them and give them as percentages in the diagrams above the joints. If this understanding is correct, it must be stated that the curves given are of little value since the load distribution and, consequently, the strains and stresses vary with the load. In fact, it would have been better if the authors had given the curves for one definite load only, as they would then be available for checking eventual calculations that may be derived. At any rate, the authors' statement that the end rivets and those near the butt have taken a greater load than the remaining ones is significant.

[45] "Zur Kraftverteilung in genieteten Stäben," by Ivan Arnovlević, *Oesterreichische Wochenschrift für den öffentlichen Baudienst*, Vol. 14, 1908, pp. 607–615.

(*11*) *Behavior of Riveted Joints.*—Last, but by no means least, elongation, slip, distribution of strains, and partition of load—in short, the behavior of riveted joints under load—will be discussed. All these factors are intimately interconnected, but are dealt with separately herein.

(a) Elongation.—Unfortunately, the authors have not given a definition of what they wish to be understood by elongation. In lap joints, it is either the change in length of the distance between the outer ends of the plates, or the change in length between the points on the main plates, coinciding at the beginning with the outer ends of the adjoining plates. Similarly, in butt joints, elongation is either the change in length of the splice plates, or the change in distance between the points on the main plates coinciding at the beginning with the ends of the splice plates. In other words, the authors should have stated if, by elongation, they mean the elastic and plastic change in length of the plates between their ends, without the end slip, or if the elongation is to include the end slip at either end. This makes quite a difference. A clear-cut definition would have helped greatly in gaining a correct understanding.

Furthermore, the authors use a ratio of unit elongation of the joint to unit elongation of the gross-section of the main plates, which, for lap joints, is shown (see Table 9) to vary from 1.03 to 3.32—that is, within wide limits. The actual law of elongation has not been discussed. However, as an "effective modulus of elasticity" for the joints of Series F, the authors give a value of about 29 000 000 lb per sq in. as against 32 000 000 lb per sq in. for the main plates. For this series, the elongation ratio varied from 0.79 to 1.13 which is about 43% on the basis of the lower, and about 30% on the basis of the higher value (see Table 17, Column (12)). The writer is unable to understand how this effective modulus of elasticity takes care of this range.

(b) Slip.—The authors also have failed to define clearly what they mean by "slip", or, rather, they have been using the term in two very different senses: (1) For the movement of an entire plate relative to another plate; and (2) for the movement of parts of one plate relative to parts of another while other parts of both plates do not move relative to one another. At places, the authors have called the former "middle slip" and the latter "end slip". The way in which the latter was measured is not beyond reproach, as the locations vary somewhat. In almost all cases, the measurements were taken in the joint somewhere between the first and second rows of rivets. Only in the short specimens, ANM–12, were they measured in the first row of rivets. However, slip occurs even ahead of the first row of rivets, and the proper position for measuring the end slip would have been directly at the end of the plates, or of the splices. It is unfortunate that this was not done as it becomes, thereby, almost impossible to compare, directly, the measured results with those derived from a rational method of calculation. The middle slip is used by the authors as an indication that all rivets have come into full bearing, and they have plotted curves of the ratio of end slip to middle slip. The latter, however, mean little since this ratio combines two different effects in it as has been shown previously herein. Unfortunately, the authors have given only typical load-slip curves and have not entered their test points in these diagrams, from which fact it may be inferred that these are idealized curves, or, at least, curves of averages. As the test points were omitted in the diagrams of the load-slip relationship, the investigator is not able to form his own judgment as to whether the curves shown are actually the best that can be passed through the test points, or if local anomalies exist, and, if so, at what loads. Apparently, the curves are faired (almost too much so), a fact that does not make them appear at all likely where sudden slips occur. The true test points, or better still, a tabulation of the test readings, would have been of far greater value for comparisons between tests and calculations.

The load-slip relationship of the joints (representing their load-elongation diagram, which is akin to the stress-strain curves) has been divided by the authors into four stages. With the exception of the first, these stages have been described more or less accurately. Regarding the exception, they state: "In the first stage, static friction prevents slip." This is incorrect if it refers to end slip, but is correct if it refers to middle slip, which shows clearly the ambiguity of the term "slip" as used in the paper.

Of interest are the authors' statements regarding sudden short slips and snaps which occurred in Series F. The writer believes that it would be much appreciated if one could see some of the actual load-slip curves (including all test points) which exhibit these short slips.

The authors are partly correct in stating that the slip has little influence on the elongation. This statement holds true for the later stages; but it does, or does not, hold true for the last part of the first stage, according to the definition of elongation chosen. That the more ductile steels exhibit less middle slip than do the harder steels is well known, particularly from shipbuilding. The unknown fact, however, is how much the slip actually is; and this depends on the friction factor, the state of the faying surfaces (which is not stated by the authors), the pressure exerted by the rivets, the extent to which, and intensity with which, this pressure is distributed over the faying surfaces, the clearances between rivet shank and hole, etc.

For evolving a rational method of computation, the friction factor and distribution of the rivet pressure over the faying surfaces are absolutely essential. The coefficient of friction is required for various kinds of steel plates, in single-sided friction (single shear) as well as in double-sided friction (double shear), and for a single rivet, a single rivet row, and double rows of rivets. Before the present tests were started, the writer had requested that, at least, some tests of single rivet lap and butt joints be included. It is unfortunate that this was not done. The distribution of the rivet pressure over the faying surfaces is of importance as the friction factor depends on it. This distribution varies considerably with the thickness of the plates.

Of interest, also, is the statement by the authors that, in the lap joints of Series A, the working load of the rivets, for most joints, fell in Stage II, but that for nickel-steel joints with manganese-steel rivets, it fell in Stage III. Hence, it seems as if such nickel-steel joints might be calculated according to the elastic theory only (Ivan Arnovljević, Cyril Batho, and Alexander Hrennikoff, Assoc. M. Am. Soc. C. E.). Another interesting fact may be mentioned—namely, that in butt joints the end slip proved to be about three-fourths of that of lap joints of similar proportions.

(c) Distribution of Strain.—The authors are to be commended for having attempted the arduous task of establishing the strains and, thereby, also the stresses over the full width of the main plates in the joint for, at least, a few joints. The picture revealed thereby is illuminating. It shows that, with the exception of the area near the rivet holes, the longitudinal strains are distributed fairly uniformly across the joint. There is only one drawback to the results obtained—namely, that they were derived by the use of a rather long gage length (2.5 in.). For this reason, the resulting strains are more or less average strains between rivet rows. Since the strains and stresses vary sharply from point to point near the rivet holes, the authors could not possibly have detected the actual strain distribution in the vicinity of the holes with the strain gages they were using. How the distribution of the strains and stresses around a rivet hole, filled by a rivet and transmitting forces from the rivet to the plate, or *vice versa*, actually looks may be seen from the data published by A. Hennig[46]. It would have been very interesting, in the light of what has been written previously herein about the grooving effect, if the authors had also determined the variation of the strains from point to point in a line along a rivet row—that is, transversely between rivets. However, extensometers of extremely short gage length would have had to be used in that case to obtain any accuracy at all.

From the diagrams of Fig. 11, however, it appears as if the strains have not been plotted correctly; or, rather, that the curves drawn through the plotted points do not represent the strains correctly. For example, in the diagram at the extreme upper left-hand corner of Fig. 11, the face strain labeled 1, starting from the left end, should remain constant in Plate 1 until, at least, the edge of Plate 2′. From then on, it should decrease to the first gage point between the first left-hand row of rivets and the second row, and, thereupon, follow the full curve shown by the authors, to its right end, from where the strain should drop to zero at the right-hand edge of Plate 1. The same holds true for the face strains in Plate 2′, only in reverse order. It appears that the authors have not used a sufficient number of gage points to obtain the true distribution. This also holds for the other two sets of curves in Fig. 11, but, for Specimen ACC54-1, not to quite the same extent.

If the strain, however, should actually have varied in the manner shown by the authors' curves, it would have been an indication of the fact that bending strains were present and, in that case, the strain on the opposite face of Plate 1, or of Plate 2′, respectively, should have been determined in order to eliminate the bending strains. Perhaps the authors can explain the course of the curves by giving further data.

In addition, the authors have measured the edge strains at the center of the plate edges. Their plots show that these strains do not differ too greatly from the average of the face strains, although, at places, the deviation is considerable, at least in the specimens of Series A to which Fig. 11 applies. Here, again, the long gage length used is an objectionable feature. As regards the course of the curves, remarks similar to the foregoing apply. The observations as to gage-line length apply also to the joints of Series F, for which the authors have, likewise, determined the strains, although at the edges only. More data would certainly be required for careful checks, and would be welcomed warmly.

---

[46] "Polarisationsoptische Spannungsuntersuchungen am gelochten Zugstab und am Nietloch," by A. Hennig, *Forschung auf dem Gebiete des Ingenieurwesens*, Vol. 4, 1933, pp. 53–63.

(d) Partition of Load Among Rivets.—From the measurements of the strains, the authors have determined the distribution of the load over the various rivet rows (Fig. 13). These do not seem to follow the elastic theory closely. On the other hand, if the strains plotted by the authors in Fig. 11(*a*) are used for determining the distribution of the load, as was done by the writer, one arrives at a curve (for 20 kips per sq in. in the net section of the plate) which differs from the curves of load partition plotted by the authors in the lower left-hand corner of Fig. 13, and which represents more closely the load distribution curves derived from the elastic theory. This is particularly true for the curve derived from the face strains. Unfortunately, this is the only check that can be made with the material given by the authors. It would be very desirable if further material could be published by them so as to make the tests useful to the profession.

For Series F, the authors have determined the load carried by each plate at the various points. These curves were derived from the edge strains. As has already been stated, the gage length was, apparently, too great to give accurate results. As regards the load for which the curves were plotted, this has already been discussed under Item (10) herein. Fig. 14(*b*) shows, in Diagram C, that the end rivets, apparently, take a larger share than the other rivets, but that the load in the main plate increases again at about the third outer rivet row, after it has dropped about 3% more between the second and third rivet rows. This seems, indeed, very unlikely, because it means that the load carried by the splice plates would, again, be transferred to the main plates, a fact which could only occur in the case where the splice plates are considerably more rigid than the main plates. An explanation by the authors of this behavior, which does not appear in any of the other joints (at least not at the first few outer rivet rows) would be welcomed. In the shingle joints, however, it is true that load from one main plate is first transferred to the splice plates and is then again transferred from the splice plates to the main plates. Without having more accurate data than the curves which are shown at a rather small scale, it is not possible to check the behavior of these types of joints.

(*12*) *General Remarks and Summary.*—In summing up the foregoing, the writer makes the following general observations:

The present procedure of designing riveted joints is antiquated. It dates back more than 100 years when Fairbairn, in 1838, on the basis of his first practical tests, suggested the use of the ultimate strength of a riveted joint, in conjunction with a suitable factor of safety, as the criterion for its strength at working loads. From this procedure, no progress has been made within the last century, and the enormous sums spent for testing specific joints have produced, as the only result, an enormous accumulation of incoherent data that have never been properly correlated. The fault of this procedure has been recognized by some far-sighted minds, but they have not been able to replace it by a better one. This is due to the problem never having been attacked properly, a fact that was revealed to the writer by the study of the world's literature on riveted joints[26]. The deeper reason for it is that every one dealing with this problem has attempted to generalize (extrapolate) from individual experiments instead of to follow the opposite "path" of investigating, first, the underlying general and basic laws, and of particularizing (interpolating), then, by applying them to the specific problem or joint under consideration. The numerous and costly tests conducted to date might then have served as valuable checks and would have quickly revealed either the correctness or incorrectness of the theory, or its weaknesses.

Although the authors, obviously, had the best intentions of making these tests a basis for obtaining useful information and a clear insight into the behavior of riveted joints, very little has been accomplished that was not known previously, as has been shown herein. Therefore, these tests must be regarded as having, primarily, added further statistical material, obtained at ultimate loads, to the already enormous amount of such statistical information available. The load-slip relationship has been cleared up somewhat, but the published data are insufficient to permit any rational theory of riveted joints, that may be devised, to be checked by them. The tests have failed to produce those basic data which are necessary for establishing a rational method of calculating riveted joints. No such method has been published as yet. Unless such a method is established by logical reasoning, which will give results that agree with practical measurements, it cannot be said that the problem of riveted joints has been solved completely.

The present method of calculation should be revised, at least so as to make the yield load the deciding factor and to give more weight to the behavior of riveted joints at working loads. In effect, this is a procedure similar to that recommended in the theory of limit design[44].

As regards the establishment of a rational theory of riveted joints, the following should be kept in mind:

Friction, which is frequently regarded as of doubtful value, provides the supporting force in most structures. Bearing of the rivets against the plates occurs only under exceptional conditions. In ships, for example, which, in heavy seas, are subjected to constant reversals of forces—that is, to alternating stressing—rivets, when cut out, seldom show any evidence of bearing; and yet, the joints of ships creak and squeak in heavy seas, an evidence of slip occurring under friction. No deterioration of the plate material on the faying surfaces has been observed, however. Riveted plate girders with splice plates in the web scarcely ever show evidence of the rivets bearing against the plates. They are held together rigidly by friction, as has been proved by tests. These are only a few examples showing the importance of friction as the supporting force. For this reason, friction in riveted joints should be studied extensively and far more than has been done in the past.

No information is available on how the rivet force used for clamping plates together spreads in these plates, nor how far its influence extends over the faying surfaces—that is, where the quilting action, or the lifting off of one plate from the other, starts. It is obvious that this influence depends on the rivet diameter, the diameter of the rivet head, and the thicknesses of the plates clamped together. To prevent over-stressing of the plates, the smallest possible pressure of the ram of the hydraulic riveter should be used, just sufficient to form the head properly, and the ram should be held on the finished rivet until it has cooled sufficiently in the shank to prevent plastic deformations in it during further cooling. Thus, the uncertainty of the rivet clamping force would be largely eliminated. The holes and the rivet shank in finished joints should be measured so as to obtain accurate information as to the clearance space between rivet and hole. Thus, basic data would be supplied for making a rational calculation of riveted joints possible.

As to specific recommendations, the writer offers the following, of which some coincide with similar ones made by the authors:

1. Riveted joint design should be based on the stress distribution along the joint, produced by the longitudinal forces, and particular emphasis should be placed on the stress peaks near the rivet holes;
2. Riveted joint design should be based, furthermore, on the distribution of the rivet clamping force (perpendicular to the plates), with particular emphasis on the extent to which, and the intensity with which, the rivet force spreads over the faying surfaces;
3. Chain riveting (full-row riveting) should be adopted generally;
4. Rivet pitch and gage-line distances depend on both the rivet diameter and the plate thickness;
5. Friction coefficients for various plate and rivet materials at rivet pressures should be determined;
6. Riveted joints should be laid out with reference to the yield strength on which working stresses should be based;
7. Riveted joints should be as short as possible (butt rather than shingle type); and
8. In general, carbon-steel rivets are more satisfactory than rivets of alloy steels except where it is necessary to save as much in weight as possible.

E. C. HARTMANN,[47] AND MARSHALL HOLT,[48] ASSOC. MEMBERS, AM. SOC. C. E. (by letter).—Referring to the heading, "Recommendations Applicable to Design," the writers were particularly interested in Statements (1) and (2). Regarding Statement (2) that "There is no justification for elaborate formulas to calculate the effect of rivet stagger on net section," the writers have assumed that "elaborate formulas" refer to Equation (3) taken from the specifications of the American Association of Highway Officials[12] (A. A. S. H. O.) and identical in effect with that in the A. R. E. A. Specifications. Having used this method of computing net section with satisfactory results, and having frequently tested riveted joints with efficiencies in excess of 75%, the writers decided to review the test results to check the authors' recommendations.

Figs. 25 and 26 show the types of specimens tested and Tables 32, 33, and 34 show the detailed test results. These specimens are from various investigations and do not represent a single planned series of tests. Some are too small to be considered structural joints in the ordinary sense, but these can be treated as scale models of structural joints.

In dealing with rivet sizes ranging from 3/16 in. to 7/8 in., it would be misleading to add the same fixed amount (1/8 in.) to the rivet diameters in arriving at the sizes of holes to be deducted. Therefore, all holes to be deducted were assumed to be 15% larger than the rivet diameter, a percentage which is consistent with current practice when applied to the range of sizes from 3/4 in. to 7/8 in.

Table 35 summarizes the test results and includes a parallel tabulation of the results of some of the tests made by the authors and some described in the authors' references. This table shows that each group of riveted joints had one or more joints with efficiencies considerably in excess of the 75% which the authors recommend as the useful upper limit for practical design. This indicates that possibly the authors' first recommendation is too conservative. Table 35 further shows that the commonly used A. R. E. A.-A. A. S. H. O. method of calculating net section gives predicted loads which average within 11% of the actual ultimate loads for a wide variety of joints in several different materials. This spread is not excessive when compared with the accuracy expected of other design formulas such as those for column strength, allowable compression in beam flanges, and spacing of web-plate stiffeners.

than the relatively simple method outlined in the present A. R. E. A. Specifications. The only feature of this method which is open to serious criticism is its tendency to encourage inexperienced detailers to go too far in omitting rivets in the outside rows. It would seem that this weakness of the method could be easily overcome, without sacrificing any of the advantages of the method, by some simple restriction on the maximum spacing of rivets in the outside row. For example, a statement similar to the following, added to the article on net section in the A. R. E. A. Specifications, would serve the purpose:

TABLE 35.—COMPARISON OF MAXIMUM EFFICIENCIES AND RATIOS OF PREDICTED TO ACTUAL ULTIMATE LOADS*

> The transverse distance between rivets in the outside row shall not exceed eight times the nominal diameter of the rivet, and the edge distance for the end rivet in the outside row shall not exceed four times the nominal diameter of the rivet.

RAYMOND E. DAVIS,[49] GLENN B. WOODRUFF,[50] MEMBERS, AM. SOC. C. E., AND HARMER E. DAVIS,[51] ASSOC. M. AM. SOC. C. E. (by letter).—Such value as these tests may have in developing a concept of the action of riveted joints under steady loads has been enhanced by the interpretation of the results of these and other tests by the several discussers. The writers express their appreciation to those who have given their time to analyze the results and present their conclusions.

Considerable discussion has centered about the matter of design provisions for the calculation of net area in a riveted tension member. Former experimenters have noted that the customary omission of rivets at the edge of a connection has little effect on its strength, and no priority was claimed by the writers in pointing out that the effective net section of a member, as determined by experiment, does not agree with results obtained from formulas in common use. However, since designers have not generally recognized this fact in practice, the writers emphasized it by the proposal that riveted tension members be designed on the basis of their gross area. In making this proposal, the writers were aware that the data did not prove conclusively that such a procedure would represent the best possible practice. Additional analyses of the data of these and other tests, made by the various discussers, have confirmed the writers' belief that adoption of the proposal would make for an improvement over present practice.

---

[49] Prof., Civ. Eng., Director, Eng. Materials Laboratory, Univ. of California, Berkeley, Calif.

[50] Cons. Civ. Engr., San Francisco, Calif.

[51] Associate Prof., Civ. Eng., Univ. of California, Berkeley, Calif.

It has been pointed out that the suggested unit stress of 16 000 lb per sq in. on the gross section for carbon steel is the equivalent of 21 300 lb per sq in. on the net section, and that such a unit stress is higher than permissible. Table 26 of Mr. Winter's discussion shows the close relation between the stress computed on the basis of the least net area and the strength of mill coupons. Such studies show that the unit stresses proposed are approximately those that obtain under the present practice of designing for 18 000 lb per sq in. on net section and taking the usual care to protect net section. Mr. Goodrich asks that designers be given a chance to use their ingenuity in protecting the net section. The writers believe that these attempts at ingenuity generally result in a design that has less efficiency than one in which the attempt to protect net section is disregarded. Mr. Goodrich mentions the case of a single hole out of an angle. Although no experimental data covering this case are known to the writers, they doubt that the ultimate strength, based on gross section, would materially exceed 75% of the coupon strength.

Professor Wilson's proposed formula corresponds very well with the available experimental data. It allows for the grooving effect with close pitches of rivets, and it properly penalizes wide pitches, although from the standpoint of practical design the formula would again tempt the ingenuity of the designer. The writers find no reason to doubt that full end riveting of the splice plates with a $\frac{G}{D}$-ratio of 4 represents as good practice as can be developed from existing information. Professor Wilson finds that this arrangement gives an efficiency of 80 per cent. To be on the conservative side the authors suggested a ratio of net to gross section of 75 per cent.

Mr. Jones' suggestion of a weld at the end of splice plates introduces a field for further experiments, and further knowledge as to the weldability of various steels may lead to economies in design. Naturally such a procedure would be limited to steels suitable for welding and might require an alloy other than silicon for tension members. Even with supplementary welding, however, the assumption should not be made (until after its truth is developed by experiment) that the strength of the splice will not depend upon the least net section.

It appears to be the consensus of opinion that friction between the plates cannot be depended upon to any material extent, and that the holes should be filled as completely as possible. Mr. Goodrich feels that the optimum with respect to filling of holes by rivets has been reached. Possibly specifications for steel structures should fix tolerances for the diameter of rivets and for the size of the holes. In the case of the San Francisco-Oakland Bay Bridge both the quality of fabrication and the standards of inspection were above the usual commercial standards. The measurement of rivets and holes, by calipers, developed the fact that the rivets were generally undersized and the holes generally oversized. Field tests of driving rivets developed that, with the field connections reamed, there was no trouble in entering the rivets when the diameter of the cold rivet was $\frac{1}{16}$ in. less than the diameter of the hole.

Mr. Goodrich disagrees with Recommendation (6) in regard to the use of manganese-steel rivets. The writers have little doubt that, in any actual design, Mr. Goodrich would agree with the writers as to joints, including gusset-plate connections, in which manganese-steel rivets should be used. The writers feel that, in general, present design practice tends toward the extreme in attempts to reduce weight of steel in structures, and that alloy structural steel or rivets should be used only when the economies gained by using the higher-strength materials are distinctly worth while.

The writers believe that Mr. Shearwood's criticism of the description of the action of riveted joints arose from his failure to realize that the action as shown in Fig. 1(*b*) was based on a simple specimen with only two rows of rivets. The action shown by Fig. 1(*d*) is representative of the cases illustrated by Mr. Shearwood. In this latter case, end slip occurs at very low average intensities of stress on the rivets; middle slip does not start until after considerable slip has occurred near the end of the joint.

Mr. Shearwood's suggestions as to cold-driven rivets open another field for further development. At present, the equipment for driving them is so heavy that they cannot be considered for field work.

Mr. Jones suggests that the ultimate capacity of a joint will suffice as a basis for selection of design stresses. This suggestion should be applied with caution to the results of tests on large joints. As an example of data which might lead to false conclusions, the behavior of the heavier specimens of the F series may be pointed out. These specimens were designed to fail in the plates. The first failures took place in the rivets, and occurred because of yield in the plates sufficient to shear the end rivets. It is possible that if the number of rivets in these specimens had been doubled, the rivets might have failed at the same total load, and the conclusion might have been drawn that the rivets had only half the unit strength actually developed.

Mr. de Jonge's discussion is valuable in suggesting fields for further research. He has also added an interesting explanation of the failure of wide plates without rivet holes. The writers believe that a careful reading of the paper will clear up many of the difficulties expressed by Mr. de Jonge. Space limitations called for extreme brevity in view of the amount of original data presented, so that neither speculative interpretation nor presentation of extensive detailed data was possible.

A few of his comments appear to require answer. The writers are unable to agree with his main thesis in regard to the development of a "rational theory of riveted joints." Five conditions of perfect fabrication were given in the paper. To these might be added: Uniform tension in all rivets, approximating the yield strength of the rivet material. With the most perfect practicable fabrication, these conditions cannot be attained. For example, tension in the rivets of a joint may vary from zero to the yield strength of the material. Furthermore, there can be no doubt that considerable plastic action takes place at comparatively low loads, thus invalidating the assumption of elastic rivet and plate materials, on which the proposed "rational theory" of necessity would be based. Any theorizing, therefore, must be based on assumptions which cannot be met in practice.

The discussion of rivet temperatures introduces the question of greatest possible tension in the rivets *versus* completeness of filling the holes. Possibly the decision should be on the basis of type of service required of the joint. For ship plating, or for members subjected to reversals of stress, high rivet tensions may be desirable. In this case it may be that the rivet temperatures suggested by Mr. de Jonge, and the "smallest possible pressure of the ram," should be used. However, for members subjected to comparatively steady stress in one direction, the evidence is clear that slip will occur within the range of working loads. In this case it appears desirable that the holes be filled as completely as possible. To achieve this result it appears necessary to heat the rivets to as high a temperature as possible without burning them, and to use such driving pressures as to upset the shank of the rivet completely. In either case, it is desirable that the bolting up prior to riveting bring the faying surfaces into contact, and that the action of the riveter be continued longer than is usual.

In view of the foregoing considerations, the writers are unable to agree with Mr. de Jonge's Recommendations 1, 2, and 5.

The writers agree with Mr. de Jonge as to the importance of understanding the action of riveted joints within the yield range, and it was with this idea in mind that so many strain measurements were made. However, as pointed out by Mr. Jones, the indications of these tests are that the ratio of rivet yield to plate yield does not differ greatly from the corresponding ratio at the ultimate. From these and other considerations, the writers cannot agree with Mr. de Jonge's Recommendation 6.

There appears to be no reason to rule out shingle-type joints, as Mr. de Jonge does in his Recommendation 7. This type of joint is often more economical of material than a corresponding straight butt joint, and is often necessary as a means of keeping the rivet grip within reasonable limits.

It is believed that Mr. de Jonge has misapplied the idea of the "true stress-strain diagram" calculated from the test of a steel bar in tension to the detrusion failure of rivets. In the failure of structural parts or members, one is concerned with the actual load (or total load *versus* total deformation) required to cause failure, and not with a unit stress calculated by dividing the load by reduced cross-sectional area.

On the matter of joint elongation, it was the writers' intention to show that for calculations involving elongation of members such as are necessary in computing deflections, in computing secondary stresses, or in analysis of statically indeterminate structure, it is unnecessary to take the joints into separate consideration. A joint occupies only a short proportion of the length of a member. The extreme ratio of 3.32 was for a joint which probably would not be used in practice.

Messrs. Hartman and Holt have contributed valuable additional data on the problem of the effective net section; the information having to do with aluminum alloys, small rivets, and very thin plates is of particular interest.

It is pointed out by Messrs. Hartman and Holt that the use of the A.R.E.A. formula for effective net section could be applied to the results of the University of California tests to compute the ultimate loads within an average error of about 10% (range, 30%). Although this may be true, the effective net widths computed by means of this formula bore no relation to the results of tests. Close agreement was found between values of effective net width, and width determined simply on the basis of full net section, without the use of any formula. In this connection, it may be well to emphasize that the tests reported in the paper were concerned with riveted connections having a number of rows of rivets such as are used in bridge construction, rather than with connections with few rows of rivets such as are used in ship and tank construction.

Mr. Jones' suggestion that further experimentation may well be done on small specimens is well taken. As expressed in the "Introduction" to the paper, the reason for the large specimens was that those responsible for the tests felt that current practice represented too extended an extrapolation of previously existing experimental data which had been obtained from tests of small specimens. As mentioned by most of the discussers, the confirmation of major design practices was a valuable result of the investigation.

It appears that all research programs develop the need of additional ones. From the standpoint of contribution to the art of structural design, the following appear to be most worthy of additional study at the present time:

1. Further confirmation of the conclusion that greatest actual efficiency is obtained by full-row riveting;
2. Determination of the ratio between gage and rivet diameter, for most economical results; and
3. Investigation of Mr. Jones' suggestion with regard to the use of a weld at the end of splice or gusset plates.

COMBINING GEODETIC SURVEY METHODS WITH CADASTRAL SURVEYS

BY CARL M. BERRY,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. WILLIAM L. SAWYER, PHILIP KISSAM, GORDON MACLEISH, AND CARL M. BERRY.

SYNOPSIS

The purpose of this paper is to present the field and office technique developed on a large reservoir boundary survey, in which the economic consideration of the integral parts of such a survey has resulted in a more feasible and less costly treatment of land acquisition survey practise.

INTRODUCTION

The Grand Coulee Dam is situated on the Columbia River in northeastern Washington, 153 miles down stream from the point where the river enters the State. Four tributary rivers of importance—the San Poil, Spokane, Colville, and Kettle rivers—flow into the Columbia River at distances of 19, 47, 107, and 114 miles, respectively, up stream from the dam site. Numerous other streams of minor importance are tributary to the Columbia throughout the backwater area, some entering in narrow, precipitous canyons, and others across comparatively wide distributary delta plains. In all, a shore line of about 500 miles will be created by the lake behind this structure; the largest man-made structure in the history of the world. The deep Columbia Valley is characterized throughout as consisting of softly molded rolling hills and valleys, and lends itself most favorably to the development of a strong network of triangulation for co-ordination and control.

Summarized, the purpose of the boundary survey was: (*a*) To determine the extent and area of all real property situated and lying below a general taking line, or flow line, the elevation of which was fixed at 1 310 ft above mean sea level, and to fix and define the boundary lines of the area by executing a traverse of unbroken continuity lying along, or just above, the 1 310 contour; (*b*) to control the flow-line traverse properly with a network of triangulation of

such accuracy as to hold the closing errors of the traverse within the prescribed limits; (*c*) to recover or properly re-establish the original survey corners and other cadastral points established by the General Land Office and reference them to the rectangular co-ordinate system; (*d*) to furnish the Legal Division of the United States Bureau of Reclamation with analyses of chains of title, in the cases of parcels having obscure or inaccurate descriptions in previous conveyances, and finally to furnish the Legal Division with properly closed descriptions of all parcels of real property involved; and (*e*) to monument the network of control triangulation permanently and connect this network to the adjacent existing first-order triangulation of the U. S. Coast and Geodetic Survey, thus referencing the entire system of co-ordinates to the Federal network on the 1927 North American Datum.

Methods of making control surveys, within themselves, are not new to the profession; nor are the many accoutrements of retracement and flow-line surveys. The combination of the two into a single, simultaneous operation encompassing the use of instruments ranging from the simple hand compass to the 12-in. direction theodolite, and of distance determination from the woodsman's pacing to invar taping, introduces a new procedure, and is distinctly a problem in surveying economics.

SPECIFICATIONS

Early in the work, it was decided that all project co-ordination should be placed on the horizontal and vertical data commonly accepted by the twenty-three members of the Federal Board of Surveys and Maps, of which organization the U. S. Bureau of Reclamation is a member. Thus all surveys would be referenced permanently to the National network and would provide not only a lasting usefulness of all Bureau surveys to Federal, State, and local agencies, but likewise would be of advantage to the Bureau in any future work performed by other agencies in this locality. Consequently, all horizontal control was to be referenced to the 1927 North American Datum, which has as its basis the Clarke Spheroid of 1866. Vertical control was to be referenced to the 1929 level net adjustment of the North American continent.

The requirement was established that all work be "check-position"; that is, that all position computations in the field would be made by at least two independent mathematical solutions, and that by a comparison of the two routes of computation a ratio check of the actual field error would result. This ratio check was set by specifications to be not more than one part in 5 000 for all reservoir co-ordination. Both the horizontal and vertical geodetic control were to be established by triangulation and precise leveling methods, adhering to the specifications and to office and field procedure of the U. S. Coast and Geodetic Survey.

CO-ORDINATES

In 1933–34 the Bureau of Reclamation established Triangulation Station Alpha at Latitude 47° 58′ 00″.844 and Longitude 118° 58′ 29″.827 as the origin of a rectangular co-ordinate system for the Columbia Basin Project. The geographic position was determined by first-order and second-order triangulation and adjusted by the direction method to the adjacent Umatilla-49th Parallel arc of the U. S. Coast and Geodetic Survey. Rectangular co-ordinates, raised to the datum plane 1 310 ft above sea level, were then computed.[3] This grid was designated the Grand Coulee Grid Datum (GCGD), and its use was extended to a point approximately 30 miles east, and at nearly the same latitude, as Station Alpha. The practise was, after adjustment, to convert the geographic positions of the main-scheme second-order stations to grid co-ordinates; then from grid distances and bearings derived from these co-ordinates, to compute grid co-ordinates of all intersection and resection third-order stations within the figures. The scale error, increasing with the departure from the origin, had enlarged to the point at which, if use of the Grand Coulee Grid Datum was to continue, it would be necessary to compute all third-order points first on true geodetic datum and then convert individually to the rectangular grid. The reason for this proposed conversion was to smooth out, proportionately, all grid discrepancies because, with departure from the origin, the grid scale was too long with respect to an east and west direction, too short in a north and south direction, and lines perpendicular on the spheroid were several seconds askew from normal on the grid. Thus, although the accuracy of the plane co-ordinates was well within one part in 25 000, or first-order, at the mouth of the Spokane River, the discrepancy would approximate one part in 3 500 at the point where the Columbia River enters the State.

Toward the close of 1935 the Lambert Conformal projection tables—one covering the north half, and another the south half of the State—were published for the State of Washington. The wide-spread adoption of similar systems by other States, particularly those in the East, quickly led to the decision to place all future Bureau co-ordination over the reservoir site on the North Washington System.

RETRACEMENT

Early in 1934 two retracement parties were organized; they began at the dam site and proceeded up stream in search of the General Land Office corners, some of which had been established by contract surveyors more than fifty years before. Each party, comprising seven men, was assigned one bank of the river, and pursued its search by the stadia-transit traverse method. Where corners or their accessories were lost a random hub was set, and the party subsequently returned to re-establish the corner by the proportionate measurement method.

The following year (1935) a part of the retracement work was assigned to the triangulation party, and the time-honored "timber-cruiser" method was inaugurated on the project. Two seasoned woodsmen, well trained and experienced in finding obscure bearing trees and bits of evidence, were employed. The woodsmen, starting from a known corner, and armed only with photostatic copies of the General Land Office original field notes, a foresters' staff compass or a hand compass, paced off the required distance in a cardinal direction, and recovered or marked for re-establishment the corner sought for.

Upon arrival at the scene of a corner the retracement engineer first made the usual diligent search for evidence of the corner monument or the corner accessories, as described in the original field notes. If found, or restored either from the accessories or upon reliable parol (word of mouth) evidence obtained from some local landowner, the full description was entered on a Cadastral Retracement Record form (see Fig. 1) and the corner designated as a Type "A" recovery. Often a diligent search of old records in Court houses or abstract offices would reward the efforts of the engineer by disclosing a reliable tie from some near-by identifiable object to the now lost corner. In a few cases Court adjudications locating the positions of disputed corners would form the basis of the recovery record.

---

[3] Computed from formulas in *Special Publication No. 71*, U. S. Coast and Geodetic Survey.

Failure to recover a Type A, or original corner, would lead to interviewing the adjoining landowners for support of established fence corners. If they were found to have been established beyond the statutory length of time required for the enjoyment of peaceful occupation by the abutting owners, these points were designated as Type "B" corners, or legal corners of occupancy. Here again, all available parol evidence was entered on the Cadastral Retracement Record form, and the attest of the parties interviewed was obtained.

After all possibilities of typing a corner as "A" or "B" were exhausted, the re-establishment method by proportionate measurement, or Type "C," was resorted to, and the methods prescribed by the General Land Office manual were followed rigidly.

SIGNALING

Accompanying each retracement engineer was a signalman who, in addition to lending assistance in the recovery of the cadastral points, would determine which of three general methods was most applicable for use in co-ordinating the point. The man performing this detail of the work was an important adjunct to the organization; his ability and developed judgment reflected a marked influence on the final cost of the newly developed procedure.

Points were co-ordinated either as: (*a*) Full intersection stations, (*b*) as resection stations, by the Pothenot method,[3] or (*c*) as traverse stations.

The first method was subject to a number of variations in procedure. If a point was visible from three triangulation stations and otherwise possessed the condition of location essential to a strong "fix," it was "signaled" by placing a 4-in. by 4-in. signal pole directly over the corner-stone itself and the method of co-ordination in this case was designated "Intersection station, central." More often, however, a 4-in. by 4-in. witness post, set from 6 in. to 20 ft away from the point, was used as the signal; the distance was measured carefully and the eccentric azimuth was read from a staff compass. This method was designated "Intersection station, point near." This latter method, although introducing one additional step in the computation work, obviated the necessity of plumbing and guying a signal pole over the stone monument, which is objectionable chiefly because livestock would often push over such a signal. On the other hand, a 4-ft post, set 18 in. in the ground, was secure from this danger. Where signal posts were set beyond the 20-ft limit from the corners, the designation "Intersection station, transit eccentric" was used, and the distance and direction were obtained by the signalman with a metric-foot tape and a light-weight transit. Often the densities of Indian allotment and cemetery corners, traverse control points, and adjacent section corners, would permit observation

upon from eight to ten "transit-eccentrics" from a single setup on an intersection station.

Necessity for the second method, that of the resection, or Pothenot method, arose chiefly from three situations: (*a*) That in which the second-order observing party failed to complete each of the prescribed "cuts" to a signal, either because the signal was disturbed or because of poor light and consequent poor conditions of visibility; (*b*) that in which, because of a corner poorly located for the requirements of a strong intersection, use of a three-point-fix observation from some advantageous point near the corner would enable the observer to select and make use of other non-occupied stations, as spires, cupolas, water-towers, etc., for a strong "fix"; or (*c*) that in which, subsequent to second-order observation over an area, it was decided to co-ordinate additional corners. In deciding upon the use of this method, the signalman left the choice of the "point near" and the objects to be observed upon, to the judgment of the three-point observer. Only a flag or banner was left at the corner to assist the observing party in finding the corner.

The third, or traverse method, was necessitated where dense stands of timber prohibited the use of triangulation methods. Three such traverses were used, two along the Columbia River near the town of Lincoln, Wash. (see Fig. 2), and one on the Spokane River near Little Falls, Wash., where "fixes" at each end of the traverses made it necessary to tape only in one direction. A fourth invar traverse was taped along an old railway road-bed in the Hawk Creek Canyon, and since a "fix" was impossible at the upper end, the traverse was double-taped to meet the requirement of check position. Corners and control points adjacent to these precise traverses were co-ordinated either by metric-foot taping, or by making them intermediate angle points in transit and steel tape loop traverses of third-order accuracy originating and ending at points along the precise traverses.

TRIANGULATION

First-Order.—First-order triangulation surveys comprised a chain of 25-mile quadrilateral figures extending from the Grand Coulee dam site east and north over the reservoir area to the International Boundary, and south from the dam site over the irrigation balancing reservoir area in the Grand Coulee to Coulee City, Wash., tying in to existing stations of the U. S. Coast and Geodetic Survey at each end, and to stations of the Geodetic Survey of Canada north of the Boundary. The network thus established extended to the high mountain peaks adjacent to the reservoir areas and established solitary control stations of first-order accuracy at about 25-mile intervals slightly above the reservoir flow lines. At the same time similar control stations were fixed in position at the heads of tributary reservoirs in the San Poil, Spokane, and Kettle rivers.

Besides the two 50-m invar tapes and stretching apparatus for measuring base lines, the Bureau obtained two instruments for first-order observations from the Coast and Geodetic Survey, a 12-in. direction theodolite, and a 7-in. repeating vertical circle.

Day-time observations of double zenith distances were made upon distant helioscope signal lights, using the vertical-circle instrument. Angles were

read on each of four verniers, direct to 10″. These latter observations formed the basis of the trigonometric leveling performed over the project.

In the Summer of 1934 a camp was established on the Columbia River 60 miles down stream from the International Border. Eight men were given a rigid course of training in the many duties and responsibilities of lightkeepers. Next, their adaptability for this rigorous and exacting work of back-packing, camping, and flashing code messages with helioscopes and electric signal lights, was tested by sending them out alone for two or three nights of work on a lone mountain peak. Those men found to be qualified were given regular assignments on reconnaissance work to locate all the stations of the first-order net. The actual observing work was next undertaken; 42 first-order stations were occupied, and the geographic positions of a total of 97 points determined. Among these were a number of fire-control towers, and their positions and azimuths between towers later were made available to the U. S. Forest Service, the U. S. Indian Field Service, and the State of Washington Division of Forestry. A number of aviation beacons were likewise "cut in," and their positions supplied to the U. S. Bureau of Air Commerce. Mapping operations of the U. S. Geological Survey were in progress near Kettle Falls during the seasons of 1935–1936, and positions of a number of their topographic control flags were supplied that Bureau. Still later, a part of the first-order net was used in controlling flights of aerial photographs taken by the Soil Conservation Service. First-order control for the project extended over an area of 3 038 sq miles.

Second-Order.—Between the control stations established by first-order work along the reservoir site, a secondary network, made up of quadrilateral figures averaging 1.75 miles in axial length, was monumented and observed. Lengths were expanded into the figures at the ends of each net from base lines measured with second-order accuracy, and, after making least-squares adjustment between the control stations, the latitudes and longitudes of the triangulation stations were converted to rectangular grid co-ordinates to simplify their use in conveying tracts. Spacing of first-order control stations along the flow lines permitted breaking up the second-order work into seven nets along the Columbia River. Three additional nets extended into the valleys of the San Poil, Spokane, and Kettle rivers. Division of the nets in this manner offered the advantage of having available, for the Right-of-way Division of the Bureau of Reclamation, the final "closed" plats and descriptions of any tract, within a few weeks after the second-order and third-order work in that net had been completed.

Measurements of angles between main stations, directions to cadastral signals and flow-line control points, and double-zenith-distance measurements for trigonometric leveling, were all observed simultaneously from the second-order stations; 7-in. theodolites reading to 10″, with single, opposite verniers, were used. Although this theodolite was of the "repeating" type, all pointings were made by the "direction" method, the high quality of the circle graduations permitting this variation. On the main network, 12 positions of the circle were read, with a residual of 5 sec from the mean specified as a maximum, whereas three positions were used in pointing the cadastral signals, and the same residual specified. Use of the direction method often permitted a station to be completed in much less time than it could have been by the method of repetition, because of poor light or fog obscuring some of the signals during a part of the observing period. Likewise, the direction method obviated the necessity of making the consequent local adjustment of sum angles in the lists of direction.

The parties occupied 342 second-order stations and determined the geographic positions of 2 020 points. An example of the notes for seven of these stations is presented in Fig. 3. Second-order control for the project extended over 437 sq miles.

Third-Order.—By triangulation or traverse of third-order accuracy, or by some combination of the two, the positions of all cadastral points within, and adjacent to, the reservoir area were co-ordinated and referenced to the existing monumented stations. In most cases this was accomplished by measuring the angular directions to signals set at or near the retraced cadastral monuments or flow-line angle points; and the procedure, because of its closely related performance to the second-order work, has already been described herein. The few remaining corners which lay concealed from second-order stations were co-ordinated by three-point-fix observations made from an open spot near the concealed monument. The practical aspects of this, the Pothenot method, or Italian "metodo di Pothenot," [3] are already rather well known to professional photogrammetrists, and use of this method represents the refinement necessary to its adaptation to cadastral surveying.

Instructions to the "three-point" observing party emphasized largely the necessity of selecting stations carefully for a strong resection, and further pointed out the dangers of a "fix" lying on or near the arc of the great circle, such a fix (commonly termed a "swinger") being indeterminate. Treatment of the resection problem may be found in any good manual on plane-table surveying, and the only further mention of the procedure in this paper is of the development of an arbitrary index to the strength of any given three-point-fix, which will be found with the description of the computing form in use on this project.

Rather frequently a landowner would appeal to the Right-of-way Division to complete appraisal and survey of his tract in advance of other work in that vicinity to forestall some pending litigation, and thus save both himself and the Government considerable delay and expense by the speedy consummation of the property transaction. In that case the three-point party would co-ordinate the adjacent corners and traverse control points quickly, and the necessary plat would be forthcoming within three or four days.

The use of a standardized metric-foot tape was found most applicable for co-ordinating points within 100 ft of the control station. For points lying beyond 100 ft and up to 500 ft, or for taping loop traverses, a standardized 300-ft or 500-ft steel tape was used. A standardization site was laid out with the invar tapes, and a calibration card was compiled for each of the two lengths of tapes. These cards were given to the chainmen for field use. Mounted on cardboard, they furnished a rapid means of determining the proper plus or minus correction for various conditions of temperature and catenary. For

* Tape supported throughout.
Note.—Values above the heavy line are plus; those below are minus.

Transit angles were measured by the repetition method, the observer recording one set of $\frac{3D}{R}$, and closing the horizon.

Variations in the method of third-order co-ordination included the following: (*a*) Triangle closure at the control station, in cases where cuts could be obtained only from two second-order stations; and (*b*) observation of one line of a three-point-fix reciprocally and holding the direction of that line as fixed, where it was impossible to obtain a cut to a fourth object for a check. Such variations, although seldom used, made possible consideration of the "fix" as a "check-position."

Third-order triangulation and traverse control extended over 406 sq miles, and a total of 1 934 points were co-ordinated by surveys of this accuracy. Including the positions of the 384 monumented stations occupied, a total of 4 051 control points and cadastral corners were co-ordinated over the project.

RELATED SURVEYS

The presentation, in this paper, of material pertaining to related surveys performed simultaneously with control and co-ordination will necessarily be limited to the discussion of the economies in time and effort resulting from the easy access to local control.

Topography.—Topographic mapping of parts of the draw-down area through town sites and across tracts of relatively high valuations made full use of adjacent control, both horizontal and vertical. Plane-table sheets were prepared in advance with the grid co-ordinate system, flow-line traverse, and such natural objects as might be used for resection cuts, plotted on them. Control proved of inestimable value in mapping these isolated areas.

Photogrammetry.—A stereotopographic map extending throughout the length of the reservoir site had been prepared jointly by the U. S. Army Engineers and the U. S. Geological Survey in 1930. A limited degree of control for the stereoplotting had been provided by the latter organization by plane-table triangulation, and although a faithful representation had been made of the terrain as to the proper shapes and sinuosities of the contours, the displacement toward or away from the river of the higher contours, due to lack of control away from the river banks, left in doubt the actual amount of ownership invasion of the 1 310 contour. The terrain below 1 100 was often the extent of topographic delineation on the maps, but in general the series provided a valuable aid to the Bureau's triangulation reconnaissance.

Early in 1934 a "flight" of single-lens aerial photographs was made for the project by a private contractor. This flight extended 75 miles up stream from the dam, embracing the area of the so-called low-dam backwater. A unit of the triangulation party was detailed to signal points on the ground to appear in the aerial photos, and to perform sufficient picture-point identification work and ground control to assemble the contact prints adequately into a controlled mosaic. Control points were selected on the prints and co-ordinated by substantially the same methods as were used in co-ordinating cadastral corners, and the section corners were identified wherever possible and pin pricked by the retracement engineers. In a few instances radial plots were made from the photos to enlarge upon some feature of a special right-of-way problem. After identification had been marked on the photographs, they were handed to the right-of-way appraisal crew, and greatly aided this feature of the acquisition work. Later they were utilized in the development of the new highway and rural road system which eventually replaced the existing road system of the area to be flooded.

Hydrography.—Control surveys, both horizontal and vertical, found widespread use in the field surveys to determine backwater effect of the reservoir pool. Sounding ranges were co-ordinated quickly throughout the backwater reaches, and profiles and soundings placed on the project datum from adjacent circuits of precise levels.

Miscellaneous.—Special field surveys called for by the Right-of-way Division embraced those made necessary by inaccurate or obscure descriptions found in previous conveyances. Often large discrepancies involving excesses or deficiencies, or perhaps overlapping tracts, would necessitate a retracement of State highway, rural road, and railroad rights of way, and would require that these tracts be related to the adjacent properties. More often, an obscure point of beginning, an unclosed description, or questionable orientation, would present the troublesome feature of a conveyance. Once carefully surveyed and related to the governing system of rectangular co-ordinates, a perpetuation of boundaries would result, and would permit, at any future period, the exact re-establishment of boundary markers subsequently lost or destroyed.

FIG. 4.—INDEX MAP,

One interesting problem arose in the requirement for replacing long-span telephone crossings. The length of span and elevations of supporting towers were determined quickly by a three-point-fix theodolite observation, performing at the same time a double-zenith-distance set of observations. Elevations obtained by this method were reliable to within one foot of the true elevation.

Of no small degree of importance on the project was the exacting requirement, at the Grand Coulee dam site, for precise construction control. To provide adequate control for the building of the world's largest structure, the standard of accuracy was set at that of first-order triangulation and precise

leveling. Location of the axis of the dam, tentatively fixed by the U. S. Army Engineers some years before and marked by them with two iron pipes, was adopted subsequently by the Bureau of Reclamation as a result of its exploration studies. Projected outside the works area with the precise theodolite, the axis was marked permanently and referenced by grouting standard bronze disk markers in granite outcroppings, at points commanding a full view of the construction area. The stations thus marked were designated "east axis" and "west axis," and formed the south side of the first quadrilateral figure (see Fig. 4). Station Alpha, already set on the east bank near the center of the contractor's future town site, and Station Osborne, on the west bank in the Government engineers' future city, completed the figure. The base line was measured from Station Alpha to Station Ferry, this latter point lying on the axis of the dam at an elevation somewhat below Station East Axis.

FIG. 5.—DATA

Four steps of the survey were accomplished in occupying the stations of this first quadrilateral figure: namely—(*a*) The 1 100-m base line was expanded into the scheme, (*b*) third-order directions were measured to the near-by cadastral corner signals, (*c*) directions of first-order accuracy were measured to 40 supplemental stations established for works area control, and (*d*) observations were made on adjacent first-order stations for fixing the geographic positions and azimuths with respect to the 1927 North American Datum.

A rigid least-squares adjustment of the works area control was next performed, and a grid system, using the axis of the dam as meridian, was devised for use over the area. Supplemental grid lines, parallel and normal to the axis, were established on the near-by hills at intervals varying from 400 to 600 ft, the taping being with invar tapes equipped with spring balances and thermometers. Resulting lengths were adjusted to values furnished for each tape by the U. S. Bureau of Standards. By "wiggling-in" in two directions, any of the intersecting lines might readily be reproduced as the dam construction progressed, and thus afford an easy means of holding form-setters' chaining errors to a minimum.

In the first-order leveling, two reciprocal river crossings were observed, and 16 permanent bench-marks were established throughout the works area for vertical control.

ROUTE SHEET

OFFICE

In 1934, during the first few months of control survey activity, headquarters for both the field crews and the computing detail were maintained at Almira, Wash., the town nearest the dam site. This period of intimate contact between the two units of the organization was utilized largely in initiating the procedure to be followed in the steps of converting field data to their final form of conveyancing plat. Later the two units were separated, the field office being moved successively to Davenport, Colville, and Coulee City, Wash.; and the computing detail was stationed permanently at the dam site (Coulee Dam, Wash.). To facilitate the transmission of field data an expeditious system of data route sheets and index maps was devised (see Figs. 4 and 5).

Index maps were oriented to accommodate a maximum of area, with a minimum of overlap, without regard to cardinal orientation; 37 such maps were required over the reservoir area, and were numbered successively up stream from the dam as A441-1, -2, etc. to -28 over the Columbia River area, A441-SP1 to -SP2 over the San Poil River, A441-SK1 to -SK5 over the Spokane River, and A441-KT1 to -KT2 over the Kettle River area.

Each cadastral corner or control point co-ordinated bore a serial number, first assigned to it by the signalman, and referred to as the Signal Building Card, or "SBC" number, of the point. For indexing, the "SBC" number was assigned to the lowest numbered index map and data route sheet of corresponding number, on which it first appeared. Thus, all data pertaining to each individually co-ordinated point, including its retracement record, signaling record, co-ordination list of directions, and its intersection or three-point-fix computation, together with any subsequent correspondence pertaining to the point, were filed under the SBC number of each in the proper index map folder. Duplicate files were maintained in the field offices and at computing headquarters.

Advance sheets of the index map series were prepared in the field office as quickly as reconnaissance data were forthcoming. These sheets, locating approximately the positions of second-order stations, were compiled and blueprinted chiefly to aid the three-point party in their resection problems in the field.

The data route sheets were prepared at the field office in pencil as the work progressed. Upon completion of the work over that area, they were inked and sent with the index map to expedite the work of the computing force at the headquarters office. The data route sheet followed through each step of the field and office procedure indicating, in addition to permanent station data, the identity of the field chief performing each step of the retracement, signaling, and co-ordination, as well as that of the abstract checker. In addition, the print number of the aerial photo upon which the picture-point identification had been made was indicated, and finally the drafting and transmission record was shown thereon.

The field office provided all final values for the geographic positions of first-order stations, and the vertical angle elevations of stations in the second-order nets of triangulation. Least-squares adjustments for this work were made generally during inclement weather by members of the field parties skilled in higher mathematics. Station description cards were typed in the field office for all monumented stations and co-ordinated points, and photostatic copies of these cards were prepared for transmission to other Governmental agencies. At headquarters office, field data were resolved to final co-ordinate values, and the individual parcel right-of-way plats were prepared for the Legal Division. At this office all second-order nets were adjusted by the direction method of least squares.

Two forms were devised by Bureau computers which deserve attention, one for the intersection station solution (see Fig. 6), and the other for solution of the resection, or three-point-fix problem (see Fig. 7). Each makes provision for carrying the computation through traverse courses beyond the "fix" point to the corner sought. Instructions for the use of these forms are to be found in Appendices I and II. The mathematical formulas used in the forms are not new but the arrangement of terms is original and is believed to offer the utmost in speed where a calculating machine is available.

Intersection Computation Form.—At the headquarters office the data for coordinating most of the thousands of land monuments were received from the field offices in the form of "Lists of Directions," which were abstracted for each triangulation station of second-order accuracy and contained, in clockwise order, the names of from four to seven second-order triangulation stations and of as many as a hundred or more cadastral points (third-order stations). Opposite each name appeared the angle which the direction to that signal had been observed to make with the direction to the initial or first point on the list. The initial point was always one of the second-order stations.

FIG. 7.—THREE-POINT-FIX COMPUTATION FORM

After the office had completed least-squares adjustment work on the second-order net, each list of directions received two items which served to fix its position and orientation—namely, the Y and X co-ordinates of the occupied station and the grid azimuth of the initial direction. The adjustments of the second-order observations resulted in slight changes in the observed directions to all the second-order stations on a list, including the direction to the initial station. Thus, the initial station would have an adjusted direction slightly above or below its observed direction of 0° 00′ 00″.00; but there remained, as the point to which all unadjusted third-order observations on the list were referred, a direction of 0° 00′ 00″.00 which was no longer the direction to any real object. However, there was no confusion in this, as the fixed grid azimuth of the residual 0° 00′ 00″.00 direction was very easily computed and recorded at the head of the list. The grid azimuth of the "cut" from the occupied station to any signal is thus the sum of the grid azimuth of the initial direction and the direction to the third-order signal.

On the North Washington System of Plane Coordinates, a Lambert conformal conic projection, every cut may be represented by an equation of the form:

$$y - m x = b \quad \text{(1)}$$

The plane co-ordinates of a third-order signal may be determined readily by a simultaneous solution of two equations which represent cuts from two second-order stations. Adopting this widely used principle of analytic geometry, the computation form devised for use on this project reduces the work of co-ordinating intersection stations to a routine requiring approximately 15 min of a computer's time for each point.

Each third-order signal was observed from three second-order stations. Only rarely were the three cuts exactly concurrent; usually they formed a small triangle of error. No attempt was made to determine the most probable position within this triangle. The co-ordinates of the point of intersection of the two cuts which intersected most nearly at right angles were adopted arbitrarily as final. Third-order observations were rarely in error by more than 3″, and the cut from second-order station to third-order signal seldom exceeded 3 miles in length. Under such circumstances it appeared that the foregoing intersection point was usually within 0.15 ft of the point that would have been obtained by a least-squares adjustment of the three observations. In the computing procedure the co-ordinates of the points of intersection of the strongest and second strongest pairs of the three cuts are determined. The displacement between these two pairs of co-ordinates is also the length of the shortest side of the triangle of error. It is a valued indicator of the accuracy of the adopted co-ordinates and as such is conservative because it is probably somewhat greater than the actual error. The co-ordinates of the third and weaker vertex of the triangle of error are not computed. The form (Fig. 6) is equally adapted to use in resection problems and variations where only one or two cuts from second-order stations are available but additional observations have been made from the third-order signal to the second-order stations.

FIG. 8.—TRIANGULATION STATISTICS

Three-Point-Fix Computation Form.—The form developed on this project for the solution of the resection, or three-point problem,[4] suggests several mechanical short cuts to the computer familiar with calculating machines. The example given in Fig. 7 required 20 min for the first computer and 15 min for the checker. Among the advantages of this form are: (1) One procedure takes care of all variations of the three-point problem; (2) necessity is eliminated for preliminary inverse computations between the fixed stations; (3) all computations are performed on one sheet; there is no need for scratch-paper computations; (4) warning is furnished if a fix close to the "great circle" is being computed; the quantities $L-O$ and $M-N$ both become very small and contain less significant figures than are required for K; (5) in its elimination of inverse computations, triangle computations, and all trigonometric functions except the cotangent, this form (Fig. 7) has many features in common with the Bureau of Reclamation form, Fig. 6 (as developed on the Columbia Basin Project) for computing intersection and resection stations, etc., in which an unknown point is quickly co-ordinated by simultaneously solving two or more equations of the form of Equation (1), every direction or "cut" on the plane co-ordinate system being exactly represented by such an equation. These similarities between the latter form and the three-point form contribute mutually to the development of speed in the work of an inexperienced computer who must become accustomed to all types of co-ordination problems. A discussion of the "fix strength index," as applied to this form (Fig. 7), is shown in Appendix II.

In one of the completed second-order nets, the third-order work disclosed a maximum side closure of 0.55 ft and an average of 0.21 ft. If one assumes the average length of sight to be 8 000 ft, the average closure of a three-point-fix or of a third-order intersection station is one part in 40 000, and the poorest closure one part in 15 000. There is no question that these accuracies were consistently attained. Adjustment statistics of the first-order and second-order nets are shown in Fig. 8.

Right-of-way plats (see Fig. 9) for the Legal Division of the Bureau were prepared on scales best suiting them for binding with conveyancing forms. Characteristic data appearing on the plat for each parcel were: (*a*) Representation of the value of θ, or mapping angle, from true north, (*b*) the recitation "Grid Bearings, Distances, and Coordinates are based on the North Washington System of Plane Co-ordinates," and (*c*) the Y and X co-ordinates of two adjacent "dry" monuments and the grid bearing and distance between these monuments.

COSTS

A simplified cost keeping method was inaugurated early in connection with the control and co-ordination surveys, inasmuch as the new procedure was often subject to critical review, and further to facilitate a detailed analysis of the economies of the variations in procedure as the work progressed. The Bureau of Reclamation system of cost accounting, last revised in 1917 when the Bureau survey activities rarely, if ever, extended themselves beyond canal location and

Limited time for cost keeping by the field organization necessitated a system of simple structure, yet one which might be relied upon to give, when called for, any unit cost with accuracy. Segregations were made daily by each party chief, assigning in the proper column of the daily labor report the account number and detail symbol pertaining to his crew's work for that day. At the end of the month the office clerk added to the slip the amounts for salaries, ferry tolls, fixed office charges, material costs, etc. Transportation costs were computed on a cost-per-mile basis furnished the field office by the project cost accountant for each car or truck, and assigned at the field office to the proper job number on a mileage basis. Recapitulating accounts required only 3 or 4 hr of the clerk's time at the end of each month. Unit costs were computed and tabulated twice annually, June 30 and December 31. A partial tabulation of the field and field office costs of control and co-ordination surveys over the Columbia River reservoir site is given in Fig. 10.

FIG. 10.—COST SHEET

Final costs per acre, based on the area over which retracement was required, varied from $0.305 to $0.345 for the different annual periods over which the work extended. Retracement costs, on a "cost-per-corner-retraced" basis, amounted to $4.07 for the 3-yr period over which this activity was pursued. Many of these corners represented widely-scattered points in country exceedingly difficult to reach, found to be required for subdivision purposes many months after the first stadia retracement parties had gone over the area. Often too, the necessary search through county records would mount the retracement cost of the individual corners to as high as $25. On the tributary streams where retracement work was totally completed by the triangulation party, 643 corners were recovered by the timber-cruiser method at a cost of $2.48 per corner, or one-sixth the estimated cost of retracement by the stadia method. Likewise, the data shown for flow-line levels and traverse costs per mile are to be understood with the modification that they represent reruns of isolated sections found to be in error between triangulation control points, and are necessarily higher than costs attained over sections of continuous run.

Conclusion

Beyond the point of retracing the original General Land Office corners and other cadastral points and boundaries, the method developed presents a complete reversal of the classical, or usual "ground methods," of co-ordination. Although it establishes a precedent "beyond the previous knowledge of the Court," the method is believed well grounded in the legal elements affecting boundaries and adjacent properties, in that the mathematical determination of azimuths and distances by the inverse method is supported by the closely controlled allowable limits of closure, as well as the requirement for the position check of each point. These elements, coupled with the permanency of such a survey in connecting with a definite mathematical relationship to the Federal network, alone justify the procedure, and in light of the cost element attained, further justification for the procedure is apparent.

The writer is fully aware of the many limitations placed on work of this nature. Generally, topography and forest cover are primary factors in the economic consideration of control and co-ordination surveys; but linked inseparably with characteristics of the terrain are the following considerations: (1) The project must be situated close to points in the Federal network, or it must be of sufficient magnitude to warrant carrying in the control from some distant network; (2) there must be no compromise with the high quality of instruments and equipment required for the control part of such a survey; and (3) the selection of personnel to prosecute such a project must sedulously guard against the inclusion of any but those best qualified in their respective fields of this highly specialized branch of engineering.

Acknowledgments

Acknowledgment is made to Mr. R. E. McGowan, Assistant Bureau Engineer in charge of headquarters computing office, for his aid in developing the two computing forms, Figs. 6 and 7, with their respective instructions and commentaries, in Appendices I and II.

All the work of providing geodetic control and co-ordination over the Grand Coulee Dam Reservoir and Balancing Reservoir sites was undertaken with a field and office personnel varying from a maximum of 28 men to an average force of 15 men. The work was done by the U. S. Bureau of Reclamation on the Columbia Basin Project, with headquarters at Coulee Dam, all field work being under the direction of Frank A. Banks, Assoc. M. Am. Soc. C. E., as Construction Engineer.

All engineering and construction work of the Bureau is under the direction of R. F. Walter, M. Am. Soc. C. E., Chief Engineer, with headquarters at Denver, Colo., and all activities of the Bureau are under the general charge of John C. Page, M. Am. Soc. C. E., Commissioner, with headquarters at Washington, D. C.

APPENDIX I

Computation of Third-Order Intersection Stations

The computer about to co-ordinate a third-order intersection station will first examine a field map and determine the strongest and second strongest pairs of the three cuts, the criterion being the closeness with which the intersecting cuts approach right angles. The cut common to both pairs is designated "No. 1," the remaining cut of the strongest pair "No. 2," and the remaining cut of the second strongest pair "No. 3." Referring to the sample computation in Fig. 6, the procedure begins by entering the names of the three second-order stations, Inchelium, Elburn, and Dorr, on Lines 1, 2, and 3 in the order described. From the list of directions for Station Inchelium the following items are transcribed to the right and left of the space on the form where the station name appears:

(*a*) The Y and X co-ordinates of Inchelium.

(*b*) The grid azimuth, 224° 35′ 21″.6 (the grid azimuth of the 0° 00′ 00″.00 direction of the list).

(*c*) The direction to quarter-section corner between Sections 3 and 10; *viz.*, 29° 51′ 05″.4.

Addition produces the grid azimuth of the cut from Inchelium; written as a bearing it is N 74° 26′ 27″.0 E. Below, in the central part of the form on Line 1, Fig. 6, the equation of the Inchelium cut may be formed. The factor m in Equation (1) is 0.2784370, which is the cotangent of the angle 74° 26′ 27″.0. The sign of the mx-term is minus for cuts in the northeast and southwest quadrants and plus for cuts in the northwest and southeast quadrants. Substituting the Y and X co-ordinates of Station Inchelium in the equation,

$$Y - 0.2784370\,X = b \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

the value of b is found to be − 255 899.85. It is advantageous to perform this substitution on a calculating machine in such a manner that the $-mx$-terms and Y-terms accumulate on the dials. Similar handling of the observations from Stations Elburn and Dorr completes the formulas on Lines 2, 3, 2, and 4 in the lower half of Fig. 6, as follows:

$$Y + 0.56809446\,X = b \quad \text{(3)}$$

and

$$Y + 0.8228263\,X = b \quad \text{(4)}$$

There is also space at the bottom of the form for a combination of Cuts 2 and 3, or of a possible fourth cut.

Proceeding with the use of Equations (2) and (3), it is evident that the Y-terms are readily eliminated by subtracting one equation from the other. The X-co-ordinate, obtained by machine division, is written on the right, in the X column. The corresponding value of Y results from a substitution of the X-value in either one of the original equations, preferably the one with the smaller cotangent. This substitution may be performed entirely on the computing machine. Following the same procedure with Equations (2) and (4), the co-ordinates of the 1·3 intersection appear in the lower part of the form.

The differences in Y and X between the 1·2 and 1·3 co-ordinates are 0.03 ft and 0.10 ft, respectively. The displacement between the two points of intersection is therefore 0.10 ft, usually written in the right-hand margin of the form. As this value lends assurance that the 1·2 co-ordinates are accurate within the specified limit of one part in 5 000, these are adopted as final.

Immediately below the 1·2 co-ordinate line, space is reserved for computing the co-ordinates of the monument proper if the signal is known to be eccentric. The eccentric distance from signal to monument, seldom exceeding 2 ft, along with carefully taken compass bearings observed from the signal to the monument and to the second-order stations, is taken directly from the Signal Building Card received from the field. On the sample computation form (Fig. 6), the bearing from the signal to the monument (S 51° 00′ E) has been referred to the Y-axis of the co-ordinate system by taking the angles between the compass bearings on the Signal Building Card and applying these to the reversed bearings in Sections 1, 2, and 3 in the upper part of the form.

Computation of the eccentric step should always be checked. In actual practice the work of the original computer appears in black ink, whereas that of the checker appears in red. For the purpose of differentiating in this paper the original computer's work is shown as tall, slope figures, whereas that of the checker's appears as small, vertical numerals. The checker does not examine the equations that his predecessor has used, but instead, computes the bearings to the 1·2 co-ordinates from Stations 1 and 2, and to the 1·3 co-ordinates from Stations 1 and 3. It is convenient to fold under the upper half of the form successively on the Lines *A–A* and *B–B*; the folded edge with the 1·2 or 1·3 co-ordinates uppermost may then be laid beneath the co-ordinates of Stations 1, 2, and 3 on these lists of directions and the sight differences in Y and X may easily be obtained by subtraction. Dividing the Y's by the X's gives the check cotangents which reproduce the foregoing bearings checked in Sections 1, 2, and 3, thus verifying all the computations leading to the adopted co-ordinates.

APPENDIX II

COMPUTATION OF THIRD-ORDER THREE-POINT-FIX STATIONS

The computer about to co-ordinate a three-point-fix station will first examine a field map and, noting thereon the relative positions of the fix and the four second-order stations observed, make the selection of the three stations which will constitute the strongest fix. The fourth object, in this case Station Mitchell, is reserved for checking purposes. Hence, Stations Sixmile, Ninemile, and Jensen become Objects 1, 2, and 3, respectively, on the computing form (see Fig. 7). (If the point sought happened to lie within the fixed triangle Sixmile-Ninemile-Jensen, any one of the three fixed stations could be designated Object No. 1; No. 2 and No. 3 would follow in clockwise order.) The names of the four stations are written on the lines labeled 1, 2, 3, 2, 2, and 4 in the upper half of Fig. 7. The known Y and X co-ordinates of these stations are entered in the spaces to the right of their names. From the List of Directions the three angles $1 \cdot 2$ (α), $3 \cdot 2$ (β), and $2 \cdot 4$ are obtained by subtracting mentally and entering in the spaces provided on the form. The cotangents of α and β, taken from tables, are copied on the lines labeled "cot α" and "cot β." (Interpolation between the interval values given in the tables is an operation of only a few seconds on the calculating machine. For an angle greater than 90°, the cotangent is negative, of course.) Fig. 7 is self-explanatory as the computer proceeds down the right-hand side of the form to Line L–O and Line M–N. When these two terms are divided as indicated on the left-hand side of the form, they produce the quantity K. Directly below this quantity, $K^2 + 1$ may be developed. To the right, substituting values in either of the two expressions $\frac{(K\,O + M)}{(K^2 + 1)}$ or $\frac{(K\,L + N)}{(K^2 + 1)}$ produces Q, which is written in the space provided on the extreme right. Immediately to the left of Q is a space for the term $K\,Q$. Adding algebraically produces the position co-ordinates of the "Point Near," the name given to the point sought or that point from which the three-point observation was made. The minus signs before the Y and X coordinates of "Point Near" should be ignored at this time but will be found to be somewhat advantageous in the checking operation involving Station Mitchell. In cases where the value of K is greater than unity, Q may be a small quantity; in such instances Q should be evaluated to several places of decimals, as these significant figures will be essential to accuracy in developing the value $K\,Q$.

At this stage of the computation, the problem has been solved to the extent of determining the co-ordinates of the three-point-fix. An experienced computer performs this much of the computation in 12 min. The remainder of the form is used for checking both the field and office work and for resolving the co-ordinates of the "Point Near" through the short traverse step to the coordinates of the concealed monument, in this case the quarter-section corner between Sections 14 and 23.

Returning to the use of the fourth object, Station Mitchell, the computer makes the algebraic subtraction indicated where the co-ordinates of Station

Mitchell have been written. Dividing + 15 228.32 by − 1 811.40 results in a value which is the cotangent of the bearing to Station Mitchell; evaluated on the left this bearing is N 6° 47′ 00″.3 W. On the third line above this may be written the bearing to Station Ninemile, derived from K, which is the cotangent of the bearing to Ninemile; the quadrant in which this bearing lies is determined by reversing the algebraic signs of the quantities $K\ Q$ and K. Adding (clockwise) the observed angle 75° 35′ 34″.2 again produces a bearing to Station Mitchell, N 6° 47′ 01″.8 W, which is 1″.5 divergent from the Mitchell bearing previously obtained. This quantity (1″.5) is a measure of the accuracy of the field observations given in the List of Directions, provided: (*a*) The office solution has been free from error, (*b*) the rectangular co-ordinates of the four second-order stations are entirely accurate, and (*c*) the fourth object is so situated that it offers a strong check against the other three.

The computer who has completed his work to, and including, the line "Bearing Difference" (Fig. 7), finding the field data checking satisfactorily, proceeds to the bottom part of the form and makes the simple traverse computation to develop the co-ordinates of the quarter-section corner-stone. His initials, F. S. B., at the top of the form, indicate he has abstracted these co-ordinates.

A second computer checks the first man's work but follows a partly independent procedure which begins with the assumption that the co-ordinates of the "Point Near" are correct. He first verifies the three angles α, β, and 2·4. Next, in the center part of the form, he makes the subtractions 1-Pt.Nr., 2-Pt.Nr., and 3-Pt.Nr. in the Y and X columns. (This subtraction is performed most simply by folding under the top half of Fig. 7 above Line A–A on the sample and then successively placing the folded edge directly beneath the co-ordinates of Stations Sixmile, Ninemile, and Jensen where they are listed on the abstract sheets; the subtraction is thus made without copying down any figures.) Dividing the Y-values by the X-values produces cotangents and consequently, on the extreme left in Fig. 7, the bearings from "Point Near" to Objects 1, 2, and 3, respectively. Bearings 1 and 2 should reproduce α, and similarly, Bearings 2 and 3 should reproduce β, thus checking the office work that produced these co-ordinates for "Point Near." Below this line the second computer checks all the work of his predecessor.

Use of the Fourth Object to Check the Observations

On the line "Bearing Difference," the value 1.5 sec is of little aid in deciding whether a specified accuracy of one part in 5 000 is being met. Therefore, the estimated length of the line between "Point Near" and Station Mitchell, 15 300 ft, is multiplied by the sine of 1″.5 to give 0.11 ft, which value, in turn, is divided by the sine of the angle 4·2 to produce the ultimate index of accuracy, the figure on the extreme right-hand end of the line which, in this particular example, remains 0.11 ft. The experienced computer can usually determine the terms on this line mentally and without resort to tables. The last angle is not always 4·2 but, rather, is the angle between the direction to 4 and whichever of the other three objects will produce the angle nearest to a right angle. This entire procedure that involves the fourth object is entirely arbitrary;

the reason for performing it in this manner may be seen in the following review of three-point problem computation where a fourth object is available:

(*a*) Mr. W. F. Reynolds has shown[5] the method of combining all four directions in a least-squares adjustment. This ideal method, of course, is not intended for general engineering use.

(*b*) The suggestion of making two different solutions is made by the U. S. Coast and Geodetic Survey,[6] which omits one of the four objects in the first solution and omits a different object in the second solution.

(*c*) A variation of Method (*b*) is popularly used because it is quicker and apparently furnishes as faithful a check. This method may be illustrated by a solution of the Bureau of Reclamation sample three-point problem on Coast and Geodetic Survey Forms Nos. 655 and 25. The fourth object, Station Mitchell, is introduced only in the fourth triangle on Form No. 25. In that triangle, the second angle is obtained by subtracting the known fixed angle, Jensen-Ninemile-Mitchell, from the second angle of the second triangle. The common side of the fourth triangle disagrees by 0.13 ft with the side in the first and second triangles. Values greater than 0.13 ft would appear if the fourth triangle were Point Near-Jensen-Mitchell or Point Near-Sixmile-Mitchell. The fourth triangle is always chosen so that its first angle is as near a right angle as possible. It will be noticed that this is a practice identical to that on the Bureau of Reclamation form (Fig. 7) in which the value 0.11 ft was divided by the sine of the angle 4·2, which was the angle between Station Mitchell and whichever of the other three objects produced the nearest to a right angle. If a number of examples were solved by both methods it would be noticed that the final index value (0.11 ft) on the line "Bearing Difference" in the Bureau of Reclamation form is practically identical with the check value (0.13 ft) appearing in the fourth triangle of the method of triangles mentioned. No matter which of the two methods is followed, the index or check value obtained by using the fourth object as shown in these examples is believed to be as trustworthy an indicator of the accuracy of the field observations as can be obtained without a least-squares adjustment. The average of these index values for a large number of three-point problems in a given district appears to represent the probable error in displacement for the points co-ordinated. In any one example, however, its index value does not necessarily represent its probable error in displacement because, as previously noted, a fourth object will sometimes be so situated that it is incapable of checking all of the other three directions, and *vice versa*.

DISCUSSION

WILLIAM L. SAWYER,[7] ASSOC. M. AM. SOC. C. E. (by letter).—Mr. Berry's paper is an excellent description of an extended survey, including geodetic and cadastral methods, which, until recently, were rarely associated. From the manner in which these were correlated, it is evident that careful planning was a necessary preliminary to undertaking the work. This paper may well serve as a reference for any Federal, State, or political subdivision which is undertaking an extended survey, especially where cadastral surveys are involved.

The economy claimed by the author in the execution of the work is not to be disputed. In this connection it is gratifying to note that the cadastral points were defined in terms of plane rectangular co-ordinates on the Lambert conformal projection, thus tying the cadastral surveys to a system by which lost corners may be easily recovered or replaced with precision. Thus the economy to be realized by the many advantages of plane rectangular co-ordinates wil be extended into the future. Philip Kissam, Assoc. M. Am. Soc. C. E., has discussed these points in an excellent manner.[8]

The writer doubted the advisability of using 7-in., 0° 0′ 10″ repeating theodolites as direction instruments on second-order triangulation until noting the results of triangle closures in Fig. 8. The requirements of the U. S. Coast and Geodetic Survey[6] for second-order triangulation angles are, for average triangle closure, 0° 0′ 3″, except that an effort should be made to keep the average closure down to 0° 0′ 2″.5, and that the maximum closure should seldom exceed 0° 0′ 6″. With one exception (arc Kettle 3″.38) the triangle closure is less than 2″.5. The maximum triangle closure ranges from 4″.45 to 7″.64. In the opinion of the writer these results are worthy of note, considering the program of observing used. Doubtless, the accuracy obtained is due primarily to two points given in the conclusion and emphasized herein: The use of high-quality instruments and the selection of the best qualified personnel. The writer doubts the advisability of attempting second-order and third-order triangulations by the program outlined in the paper, except for those surveying organizations best equipped in personnel and instruments.

PHILIP KISSAM,[9] ASSOC. M. AM. SOC. C. E. (by letter).—The method of cadastral surveying described in this paper might well be used as a standard wherever cadastral surveys are made simultaneously over a large area. The paper is so inclusive and so well condensed that it might almost serve as a manual for this type of surveying.

There are a number of points that Mr. Berry describes which should be emphasized strongly and which are sometimes neglected in surveys of this kind. First, it is evident that all control survey points are monumented and marked with identifying numbers; descriptions of them are written and placed in a permanent record. This means, of course, that the survey is permanently located on the ground and it can be rerun for the purpose of locating any points that may be lost. Second, the work has been done according to the specifications of the U. S. Coast and Geodetic Survey, which means that the precision of the control is such that it can be made part of the fundamental triangulation net of the United States and, therefore, is available for use by any surveying agency. Third, the results have been computed in terms of the State plane co-ordinate systems, which means that there are available thousands of monumented positions within the area covered by the survey which have been determined in terms of these co-ordinates and therefore are useful as a basis for all types of surveying without the knowledge of geodetic reduction. Since the entire control system has been based on the accepted fundamental datum of the United States, the plane co-ordinates of these stations are the accepted plane co-ordinates recommended by the Federal Bureau of Surveys and Maps and contain an exceptionally low-scale correction.

[8] "Proposed Improvements for Land Surveys and Title Transfers," by Philip Kissam, *Proceedings*, Am. Soc. C. E., April, 1939, p. 573.

[9] Associate Prof., Civ. Eng., Princeton Univ., Princeton, N. J.

With an arrangement of this kind the average land surveyor will be able to determine the State plane co-ordinates of all points on his surveys within reasonable distance of the points thus established. Thus, all surveys in that area can be easily referred to the same datum. The control points cannot be lost, and the positions of property lines can be so described that they are permanent in position. The advantages of a definite standard plane rectangular datum are so numerous that the decision to use such a system cannot be overemphasized.

The adoption of methods that tend toward the reduction in costs as well as the improvements in accuracy are excellent, and the careful cost accounting method used should be emulated. Of particular interest is the method of using long tapes—that is, tapes from 200 to 300 ft long for third-order traverse. Utilization of long tapes is a great timesaver, and it is especially important that the taped distances are corrected for slope rather than an effort made to hold the entire tape in a horizontal position. The simplicity of Table 1 makes possible the field reduction of all measurements and eliminates the necessity for too rigid standardization of methods of support which are necessary when computation is made entirely in the office. It is believed that further economies could have been obtained had a more modern, simultaneous-coincidence, micrometer transit been substituted for the 10-sec repeating instrument used for second-order triangulation. Accuracy, speed, and reduction in the first costs would probably have been obtained, if such a transit had been used, together with the advantages of using an instrument which would have been far easier to transport. The utilization of plane co-ordinates for practically all computation subsequent to the determination of geodetic position for first-order and second-order triangulation and control traverse is to be commended, and attention is drawn to the reduction in computation costs which this provides without, however, departing from a standard datum.

The right-of-way plan illustrated in Fig. 9 is exceptionally complete. However, there is no note or legend which indicates whether the bearings given are true bearings, or grid bearings, and it would seem proper that grid bearings only should be used and so noted.

The entire survey seems to have been well thought out and the administrative details nicely standardized. Mr. Berry is to be complimented upon his fine contribution.

GORDON MACLEISH,[10] ASSOC. M. AM. SOC. C. E. (by letter).—The engineer in charge of any extensive survey should find this paper of great interest. The methods described by the author for assuring accuracy in the work and for maintaining a complete historical record of all points established and co-ordinated are excellent; and the paper shows clearly the value of systematizing, carefully, the field and office procedures and arranging the observations and measurements so as to give the required information with the greatest economy of effort. It is to be hoped, also, that the paper will receive the attention it deserves from the legal profession and from the judiciary because, as the author well remarks, the indirect methods, although in many cases much more accurate than the orthodox "ground methods," are too often "beyond the previous knowledge of the Court."

The methods given by the author for the co-ordination of an intersection station and of a three-point fix (Figs. 6 and 7) are very concise and, if co-ordinates only are wanted, require a minimum of trigonometric functions to be looked up in tables and entered on the form. It often happens, however, that the bearings and distances are required as well as the co-ordinates; and in such cases it is necessary, of course, to look up the usual sine and cosine functions and to use additional lines for their computation; and still further work is required to check these quantities after they are computed.

It seems to the writer that the retention of tenths of seconds in angles and bearings in the computation of third-order intersections and three-point problems is a refinement that is scarcely warranted by the strength of such fixes. In Fig. 6 the location of the point from Inchelium and Dorr would be changed by only 0.01 ft, and in Fig. 7 the three-point fix would be changed by only 0.02 ft by using the nearest even seconds; and much time would be saved in the computations. When the use of tenths of seconds is justified it might be advisable to consider also the effect of the azimuth corrections in computing the longer fixes. A method of doing so will be given subsequently herein, whereby grid co-ordinates may be computed accurately from geodetic angles for lines of any length up to 25 miles or more, the length being limited only by the accuracy with which the azimuth correction terms can be computed.

The method given for the computation of an intersection station (Fig. 6) has the disadvantage of requiring the use of at least a ten-bank calculating machine unless the co-ordinates are all small; and even in that case the quantities m and b in Equation (1), or K in Fig. 7, may still be very large. This will be the case whenever the line in question is nearly north and south. It frequently happens, too, that an intersection or three-point fix is required in the course of a traverse, in which case it is very convenient to use a method of computation that utilizes the ordinary traverse form. The writer uses the following methods which he finds very quick and simple, and which he prefers for the reasons that:

---

[10] Cons. Engr., Santa Barbara, Calif.

1. A simple traverse form is used, whether for an intersection or a three-point, both of which are computed by the same process; and an eight-bank machine is large enough for all problems;

2. The calculations give, directly, the distances to, as well as the co-ordinates of, the unknown point, and are entirely self-checking for all quantities involved;

3. All trigonometric functions used are less than unity, thus requiring tables of tangents only up to 45°;

4. All digits on the left in either co-ordinate column that are common to all points may be disregarded without affecting any part of the work;

5. No unusual entries are required in the traverse form except the values of the tangents of the bearings; and

6. All three-point fixes are computed in the same manner whatever the relative positions of the points, the only effect of position being the addition of 180° to one or another of the bearings.

The time required by this method to calculate and check a three-point fix, including bearings and distances, is about the same as by the author's method; and for an intersection point it is probably a little less.

Consider first the solution for an intersection point, since this is the basis also of the three-point solution. Suppose Point P (Fig. 11) to be located by cuts from the known points A and B.

Let $\Delta x_{AB} = x_B - x_A$; $\Delta y_{AB} = y_B - y_A$; α and a = bearing and length of $A\,P$; and β and b = bearing and length of $P\,B$. It is evident from Fig. 11 that

$$\Delta x_{AB} - a \sin \alpha = (\Delta y_{AB} - a \cos \alpha) \tan \beta \ldots\ldots\ldots\ldots (5a)$$

and

$$\Delta x_{AB} - b \sin \beta = (\Delta y_{AB} - b \cos \beta) \tan \alpha \ldots\ldots\ldots\ldots (5b)$$

Whence,

$$a = \frac{\Delta x_{AB} - \Delta y_{AB} \tan \beta}{\sin \alpha - \cos \alpha \tan \beta} \ldots\ldots\ldots\ldots (6a)$$

or

$$a = \frac{\Delta y_{AB} - \Delta x_{AB} \cot \beta}{\cos \alpha - \sin \alpha \cot \beta} \ldots\ldots\ldots\ldots (6b)$$

$$b = \frac{\Delta x_{AB} - \Delta y_{AB} \tan \alpha}{\sin \beta - \cos \beta \tan \alpha} \ldots\ldots\ldots\ldots (7a)$$

or

$$b = \frac{\Delta y_{AB} - \Delta x_{AB} \cot \alpha}{\cos \beta - \sin \beta \cot \alpha} \ldots\ldots\ldots\ldots (7b)$$

As shown subsequently, the method of using these formulas is such that only their general form need be remembered.

The signs of the functions of the bearings are in strict accordance with the co-ordinate system used—that is, for the usual system as shown, a bearing in the northeast quadrant has all functions positive; a bearing in the southeast quadrant has the sine positive, the cosine negative, and hence the tangent

$\left(\frac{\text{sine}}{\text{cosine}}\right)$ negative, etc. The distance a may be found from either of Equations (6); but in order to keep all quantities as small as possible Equation (6*a*) is used if β is less than 45° and Equation (6*b*) if β is greater than 45°. Thus, tables of tangents to seconds of arc beyond 45° are not needed, and no function is greater than unity. Knowing a, the co-ordinates of Point P can be calculated, whence b becomes known as that distance necessary on the bearing β to reach the co-ordinate of Point B.

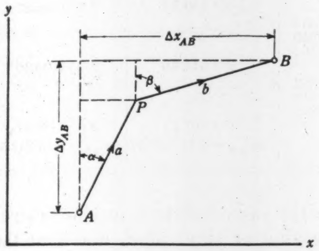

FIG. 11

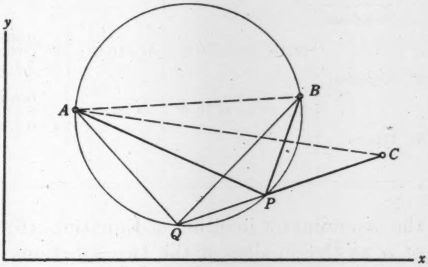

FIG. 12

By this method the solution of the author's intersection from Inchelium and Elburn in Fig. 6 (omitting the derivation of the bearings which can be inserted easily) would be made as shown in Table 2. The underlined digits in the co-ordinate columns need not be used in the computation.

Since β is less than 45°, use Equation (6*a*) and compute the denominator first, jotting it down. Then compute the numerator and without clearing it from the machine divide it by the denominator. This gives the value of a, thus,

$$a = \frac{(+\,14\,242.54) - (+\,14\,448.17)\,(-\,0.1760271)}{(+\,0.9633540) - (+\,0.2682333)\,(-\,0.1760271)} = 16\,610.23.$$

Having found the value of a, enter the y-co-ordinate of Point A in the machine and compute the y-co-ordinate of P. Then without clearing the machine enter $\cos\beta$ on the keyboard and crank up enough turns (positively or negatively) to arrive at the y-co-ordinate of Point B, the value of the distance b being given by the number of turns cranked. The x-co-ordinate column then serves as a check on the work and gives the x-co-ordinate of P in doing so. The distance b may be calculated by means of either co-ordinate column, the other serving as a check; but for greatest accuracy that column should be used which corresponds to the larger of the two functions (cosine or sine) of β. The only quantities not checked by the foregoing method are the entries of $\cos\alpha$ and $\sin\alpha$. Hence these should be verified or, as a final check, the value of b should be computed from Equation (7*a*) or (7*b*). If b is computed originally from Equation (7*a*) or (7*b*), the two co-ordinate columns furnish a double check on the entire work.

If the value of the denominator in Equation (6) or (7) is negative the numerator will be negative also, provided that the bearings are consistent with the given co-ordinates. In this case leave the numerator as a negative entry in the machine, enter the absolute value of the denominator on the keyboard and crank up positively until the result is zero. The value of a (or b) will then be given by the number of turns cranked. Note that the first term of the denominator in either of Equations (6) is the same function (cosine or sine) of α as the smaller of the two functions (cosine or sine) of β, and that the first term of the numerator is from the corresponding co-ordinate column; and this applies similarly for the use of Equations (7). If these two reminders are fixed firmly in mind Equations (6) and (7) need be remembered only as to general form, and the proper one will be chosen and used correctly almost without thought.

TABLE 2.—COMPUTATION OF INTERSECTION STATION

Point	Bearing	Distance, in feet	cos sin (tan, cot)	Y	X
A. Inchelium				$\underline{4}79\ 159.04$	$\underline{2\ 6}39\ 946.87$
	N. 74° 26′ 27″.0 E.	16 610.23	0.2682333 0.9633540 (+0.2784369)	+	+
P. X-station				$\underline{4}83\ 614.46$	$\underline{2\ 6}55\ 948.40$
	N. 9° 59′ 00″.0 W.	10 146.39 ✓	0.9848582 0.1733617 (−0.1760271)	+	−
B. Elburn				$\underline{4}93\ 607.21$	$\underline{2\ 6}54\ 189.41$ ✓
				$\Delta y_{AB} = +14\ 448.17$	$\Delta x_{AB} = +14\ 242.54$

Much time can be saved in the computation by carrying the co-ordinates (or their last seven or eight digits) continuously in the calculating machine and letting the multiplications accumulate, either positively or negatively as required. This saves writing down the individual values of Δx and Δy unless they are needed to compute a length or a bearing. They are never needed to compute areas, since cross-multiplication of co-ordinates (dropping the common digits on the left) gives the area much more quickly and with no additional columns of figures required. Thus the area of the triangle Inchelium-P-Elburn is:

$$\begin{aligned} &\tfrac{1}{2}\,[(39\ 946.87 \times 83\ 614.46) + (55\ 948.40 \times 93\ 607.21) \\ &+ (54\ 189.41 \times 79\ 159.04) - (79\ 159.04 \times 55\ 948.40) \\ &- (83\ 614.46 \times 54\ 189.41) - (93\ 607.21 \times 39\ 946.87)] = 83\ 868\ 164 \text{ sq ft.} \end{aligned}$$

This computation may be made without clearing or reading the machine until the double-area is reached. The sign of the result may be disregarded.

The following solution of the three-point problem is an analytical adaptation of a well-known graphical method, and consists almost entirely of two simple intersection computations exactly as in the foregoing.

Let Point P (Fig. 12) be located by measuring the angles subtended at P by the three known points A, B, and C. These angles may be given directly or as a list of directions from any initial. Choose, as A and B, those two of the three known points which subtend at P the angle nearest to 90°, and label them so that $A \rightarrow B$ is clockwise about P. Call the third known point C. The auxiliary point Q is the other intersection of the line $P\,C$ with the circle through A, B, and P. Denoting azimuths by α and directions by D, with subscripts for identification:

$$\alpha_{AQ} = \alpha_{AB} + (D_{PC} - D_{PB}) \dots\dots\dots\dots (8a)$$

($\pm$ 180° if P is within triangle $A\,B\,C$, or if C is counterclockwise $< 180°$ from A);

$$\alpha_{QB} = \alpha_{AB} + (D_{PC} - D_{PA}) \dots\dots\dots\dots (8b)$$

($\pm$ 180° if P is within triangle $A\,B\,C$, or if C is clockwise $< 180°$ from B). The azimuths in terms of the angles will be evident from Equations (8). Knowing these two azimuths Point Q may be co-ordinated as an intersection point by the foregoing method using Equations (6). Compute α_{QC} from differences of co-ordinates. Then,

$$\alpha_{CP} = \alpha_{QC} \pm 180° \dots\dots\dots\dots (9)$$

(or $= \alpha_{QC}$ if C is between P and Q);

$$\alpha_{PA} = \alpha_{CP} \pm 180° - (D_{PC} - D_{PA}) \dots\dots\dots\dots (10a)$$

and

$$\alpha_{PB} = \alpha_{CP} \pm 180° - (D_{PC} - D_{PB}) \dots\dots\dots\dots (10b)$$

Use Equation (10a) or (10b) whichever gives the best intersection at P with the line $C\,P$—that is, the angle at P nearest to 90°. Azimuths and angles may be carried forward easily on the calculating machine, adjusting degrees, minutes, and seconds for carry-over only at the end of the operation. By doing this repeated entries are avoided.

Point P is now co-ordinated as an intersection point as described. A final check is made by computing the third course from P by differences of co-ordinates and comparing the computed angle with the observed value. The agreement should be exact.

It is usually not known without some thought whether or not C is between P and Q, but this is of small consequence. The value of the length $C\,P$ as computed from Equation (6) should be positive; and if it comes out negative its absolute value is still correct, but the recorded directions of $C\,P$ and $P\,A$ (or of $C\,P$ and $P\,B$ if closure is made on Point B), together with the signs of their functions, should be reversed. These will be the only changes necessary, since the error in the assumed position of C will be apparent before any other value is computed.

Applying this method to the author's three-point fix given in Fig. 7, the solution would be as shown in Table 3. The underlined digits in the co-ordinate columns can be ignored in the computation, any changes in them being recorded by the machine.

The clockwise angle, Six Mile-P-Nine Mile ($= 75° 43' 02''.5$), is the nearest to 90°; so Six Mile is taken as Point A and Nine Mile as Point B, making Jensen Point C. It is evident immediately that P lies outside the triangle $A\,B\,C$, and that C is clockwise $< 180°$ from B. The azimuth of $A\,B$ is computed from Δx_{AB} and Δy_{AB}. The azimuths of $A\,Q$ and $Q\,B$ are found from Equations (8) by simple addition, using the machine to avoid duplication

of entries in the form; the azimuth of *Q C* is computed by co-ordinate differences; and the azimuths of *C P* and *P B* are found by addition using Equations (9) and (10*b*). The remainder of the work is identical with the foregoing for an intersection computation, both the points *Q* and *P* being co-ordinated in this manner using Equations (6) and (7).

TABLE 3.—COMPUTATION OF THREE-POINT FIX

	Directions	Angles
A. Six Mile	0° 00′ 00″.0	
		75° 43′ 02″.5
B. Nine Mile	75° 43′ 02″.5	
		52° 23′ 25″.4
C. Jensen	128° 06′ 27″.9	

Point	Azimuth	Length	cos sin (tan, cot)	*Y*	*X*
A. Six Mile				371 020.42	2 598 804.10

If a fourth point *D* is observed as a check, compute the course *P D* by co-ordinate differences and compare the calculated angle from one of the other points with its observed value. It is assumed that *P* will be located by the three points that give the strongest fix.

For a given set of angles the strength of a fix is dependent on the relative length of the line *Q C* in comparison with *P A* and *P B*, and decreases with a decrease in the relative length of *Q C*, the problem being indeterminate when *Q C*, or *P C*, is zero. When *P* is on the circle through *A*, *B*, and *C* either Point *Q* or Point *P* is coincident with *C*. If *Q* and *C* are nearly coincident the fix is weak. On the other hand, if *P* is nearly coincident with *C* the fix will be strong if *Q* is sufficiently distant from *C* to give the required precision to the computed azimuth of *Q C* (the strength increasing also, of course, as the measured angles approach 90°); for in this case the computed position of *P* is comparatively in-

sensitive to changes in the observed direction of $P\,C$. A three-point fix with reasonable angles observed from a point close to C (the directions of $P\,A$ and $P\,B$ being accurately measured and the direction $P\,C$ being measured approximately) is a strong fix. Hence, the usual statement that P should never be close to the circle through A, B, and C needs qualification.

Effect of Azimuth Correction Terms.—Because the azimuth correction terms in either the Lambert or the transverse Mercator projection are different for each direction observed, a geodetic or measured angle is not exactly represented by the difference between the corresponding grid azimuths. These correction terms are small and in most cases can be neglected entirely; but with long lines and high precision work in certain districts they may be large enough to be worth considering.

Since the approximate grid co-ordinates of the points must be known before the azimuth correction terms can be computed, two methods of procedure to include their effects are available: (*a*) A preliminary graphical solution may be made on a good map and the corrections computed from scaled quantities (the measured angles are then corrected and a final analytical solution made directly); and (*b*) a preliminary analytical solution is made first, using the observed angles. In Method (*b*) the azimuth corrections are computed from the resulting approximate grid co-ordinates; and from these are computed corrections to the preliminary co-ordinates of the unknown point which will give its final co-ordinates.

The azimuth corrections in seconds of arc are given by the formulas:[11]

$$\epsilon\ (\text{Lambert}) = -\frac{x_2 - x_1}{2\,\rho_0^2 \sin 1''}\left(y_1 - y_0 + \frac{y_2 - y_1}{3}\right) \ldots\ldots (11a)$$

and

$$\epsilon\ (\text{transverse Mercator}) = +\frac{(y_2 - y_1)\,(2\,x_1' + x_2')}{(6\,\rho_0^2 \sin 1'')_a} \ldots\ldots\ldots (11b)$$

in which the sub-one subscripts refer to the station at which the azimuth originates and the sub-two subscripts refer to the station at which the azimuth terminates. These corrections are to be applied to the grid azimuths with the signs as given. For an intersection computation the azimuths, α, originate at the fixed points where the cuts are made, whereas for a three-point computation they originate at the unknown point. Corrections must be computed for both sides of each angle used—that is, a correction for each direction.

Correction of an Intersection Station.—Using literal subscripts to denote the origin and terminus, the letter R denoting any reference point (for example, ϵ_{AR} is the correction to the grid azimuth from A to R), the formula for an intersection is:

$$\alpha_{AP}\ (\text{grid}) = \alpha_{AR}\ (\text{grid}) + \text{Angle } R\,A\,P\ (\text{observed}) + (\epsilon_{AR} - \epsilon_{AP}) . (12a)$$

and

$$\text{Angle } R\,A\,P\ (\text{grid}) = \text{Angle } R\,A\,P\ (\text{observed}) + (\epsilon_{AR} - \epsilon_{AP}) \ldots (12b)$$

Then the change in the azimuth of $A\,P$ (which equals the change in the azimuth of $P\,A$) due to the azimuth corrections at A is

---

[11] *Special Publication No. 193* (Manual of Plane-Coordinate Computation), U. S. Coast and Geodetic Survey, pp. 13 and 171.

$$\Delta\alpha_{AP} = \Delta\alpha_{PA} = (\epsilon_{AR} - \epsilon_{AP})\ldots\ldots\ldots\ldots\ldots(13a)$$

and, similarly,

$$\Delta\alpha_{BP} = \Delta\alpha_{PB} = (\epsilon_{BR} - \epsilon_{BP})\ldots\ldots\ldots\ldots\ldots(13b)$$

Furthermore

$$\tan^{-1}\frac{x_A - x_P}{y_A - y_P} = \alpha_{PA}\ldots\ldots\ldots\ldots\ldots\ldots\ldots(14)$$

and, taking the total differential with x_P and y_P variable, and substituting $x_A - x_P = s_{PA}\sin\alpha_{PA}$; $y_A - y_P = s_{PA}\cos\alpha_{PA}$; and $(x_A - x_P)^2 + (y_A - y_P)^2 = s_{PA}{}^2$:

$$\frac{\cos\alpha_{PA}}{s_{PA}}\,dx_P - \frac{\sin\alpha_{PA}}{s_{PA}}\,dy_P = -\,d\alpha_{PA}\ldots\ldots\ldots\ldots(15a)$$

Changing to increments and dividing by sin 1″ to change the value of $\Delta\alpha$ from radians to seconds of arc:

$$\frac{\cos\alpha_{PA}}{s_{PA}\sin 1''}\,\Delta x_P - \frac{\sin\alpha_{PA}}{s_{PA}\sin 1''}\,\Delta y_P = -\,\Delta\alpha_{PA}'' = -\,\epsilon_{AR} + \epsilon_{AP}\ldots(15b)$$

Similarly,

$$\frac{\cos\alpha_{PB}}{s_{PB}\sin 1''}\,\Delta x_P - \frac{\sin\alpha_{PB}}{s_{PB}\sin 1''}\,\Delta y_P = -\,\Delta\alpha_{PB''} = -\,\epsilon_{BR} + \epsilon_{BP}\ldots(15c)$$

As always, the signs of the functions are in accordance with the co-ordinate system. Equations (15*b*) and (15*c*) may be solved simultaneously for Δx_P and Δy_P, the coefficients being based on the results of the preliminary solution and the values of the ϵ's computed from Equation (11*a*) or (11*b*) according to the projection in use. A slide-rule may be used for the entire work.

Correction of a Three-Point Station.—At a three-point station the azimuth corrections are all based on the unknown Point P as origin; so if the directions are measured from an extraneous initial no correction need be computed for the initial since it will cancel out of the equations. Corrections will be required to the azimuths from P to each of the three fixed points A, B, and C, and to any additional point that is used for a check. The changes in the angles P_{AB} and P_{BC} due to the corrections are, in seconds of arc, $\Delta P_{AB} = \epsilon_{PA} - \epsilon_{PB}$; and $\Delta P_{BC} = \epsilon_{PB} - \epsilon_{PC}$. Angle $P_{AB} = \alpha_{PB} - \alpha_{PA}$, and applying Equation (14):

$$\tan^{-1}\frac{x_B - x_P}{y_B - y_P} - \tan^{-1}\frac{x_A - x_P}{y_A - y_P} = P_{AB}\ldots\ldots\ldots\ldots(16)$$

whence, by a process similar to that used in deriving Equations (15*b*) and (15*c*):

$$\left(\frac{\cos\alpha_{PA}}{s_{PA}\sin 1''} - \frac{\cos\alpha_{PB}}{s_{PB}\sin 1''}\right)\Delta x_P - \left(\frac{\sin\alpha_{PA}}{s_{PA}\sin 1''} - \frac{\sin\alpha_{PB}}{s_{PB}\sin 1''}\right)\Delta y_P$$
$$= -\,\Delta P_{AB} = -\,\epsilon_{PA} + \epsilon_{PB}\ldots\ldots\ldots\ldots\ldots\ldots(17a)$$

Similarly,

$$\left(\frac{\cos\alpha_{PB}}{s_{PB}\sin 1''} - \frac{\cos\alpha_{PC}}{s_{PC}\sin 1''}\right)\Delta x_P - \left(\frac{\sin\alpha_{PB}}{s_{PB}\sin 1''} - \frac{\sin\alpha_{PC}}{s_{PC}\sin 1''}\right)\Delta y_P$$
$$= -\,\Delta P_{BC} = -\,\epsilon_{PB} + \epsilon_{PC}\ldots\ldots\ldots\ldots\ldots\ldots(17b)$$

The coefficients are computed from the preliminary solution and the ϵ-values from Equation (11). Equations (17), solved simultaneously for Δx and Δy, give the corrections to the preliminary co-ordinates of P due to the azimuth corrections, a slide-rule being used throughout.

The writer is glad to observe a more extensive use of intersections and three-point fixes in geodetic and cadastral surveys that are based on accurate triangulation, provided that all such locations are checked independently as was required in the surveys described by the author. Used with discrimination and with a facile knowledge of the relations between form and strength of figure, they constitute a valuable means of locating the points whose positions are required, quickly, and with considerable, if not with the highest, precision. They are thus particularly suited to cadastral, topographic, photogrammetric, and non-urban property surveys.

The indirect methods of surveying, along with triangulation in general and conformal projection in particular, will acquire the legal and judicial sanction accorded to direct measurements and plane representation as they become more generally known, both as to detail processes and as to the results. Mr. Berry's paper is a valuable contribution toward the increase of this knowledge.

Carl M. Berry,[12] Assoc. M. Am. Soc. C. E. (by letter).—There is little question but that land-acquisition practise making use of the State-wide conformal systems, with these in turn dominated by geodetic control, is steadily establishing itself throughout the membership of the engineering fraternity. Indeed, the improvements to follow in title-transfer practise may well be stated as the logical corollaries of a controlled boundary survey, the adoption of which among surveyors, title examiners, and the inestimable host of the laity who are to some degree affected by land titles and boundaries of real property will manifest itself in the future as progress—a progress which will depend, as it has in the past, upon growth in understanding.

The comment of Professor Sawyer, wherein he "doubts the advisability of attempting second-order and third-order triangulations by the program outlined in the paper, except for those surveying organizations best equipped in personnel and instruments," is well taken. Although overemphasis of this point might, in effect, lend hesitancy to those organizations contemplating the use of control surveys, it is felt, nevertheless, that such retarded impetus would be preferable to the questionable results of ill-planned and executed projects which might otherwise result. The long-range objectives involved in the use of modern technique should not lose sight of the public-relations aspect of the problem.

Professor Kissam's discussion might well be augmented by the appeal in his excellent paper,[8] "Proposed Improvements for Land Surveys and Title Transfers," for surveyor and title examiner to combine in a joint effort to find ways and means for employing those excellent tools already at hand (modern survey equipment, skill, procedure, and established State systems of plane co-ordinates) toward eliminating boundary difficulties. His suggestion of the use of a more modern type of direction instrument is one to be considered seriously by any organization contemplating work of this nature. The writer fully agrees that the advantages pointed out by Professor Kissam would result. His further comment on the use of a note to indicate use of "grid" bearings on the right-of-way parcel plat is believed covered by the note, "Grid Bearings, Distances and Coordinates Are Based on the North Washington System of Plane Coordinates," which obviously applies to the tabulated values in the box "Reservoir Boundary," as well as to the values along section and subdivisional lines on the upper part of the sheet. Perhaps a clearer expression would result by substitution of the word "All" for "Grid" in the note, inasmuch as all values shown on the plat are in terms of "grid" values; the theta mapping angle is represented principally for the convenience of surveyors and title examiners in plotting previous deed calls by metes and bounds which would ordinarily follow "true" bearings. Plats of this type have met wide-spread favor among abstract and title companies, because of their scale representation of parcels and ownerships, and were generally used, in lieu of the usual lengthy and cumbersome typewritten metes and bounds descriptions, in negotiating the purchase contracts from landowners.

---

[12] Civ. Engr., U. S. Bonneville Power Administration, Portland, Ore.

The writer has been identified with the U. S. Bonneville Power Administration engaged in right-of-way acquisition for transmission lines in the States of Oregon and Washington, and has developed a plat embracing a square mile —one plat for each section of land invaded. Through use of a single master tracing for each section, the individual ownerships, often numbering twenty or more to the plat, are represented by coloring each parcel, a device saving much drafting room time and labor. At the same time much of the attendant possibility of errors in the preparation of the maps is removed. Although neither of these two States has yet adopted the Enabling Act, nevertheless it is felt that much groundwork has been laid toward its early introduction and passage.

The computing methods suggested by Mr. Macleish indeed look to be engagingly neat, concise, and easy to perform; certainly the forms require a minimum of written figures. As with all new designs, however, the writer would want to see an average group of computers utilize these forms for a month or so before concluding that the Macleish forms were definitely superior, the principal points of skepticism being (1) the recommendation to perform a maximum number of operations on the machine without jotting down intermediate figures, and (2) the necessity for remembering "rules-of-thumb" regarding signs of angles and choice of alternative "*a*" and "*b*" routes in the computations. Of course, most persons of ordinary ability and interest would have no trouble remembering what criteria governed in the different stages of the computations, but, as is frequently the case, not all members of the computing organization are of that caliber and for this reason it follows that whatever forms are used should be freely labeled to be as self-explanatory as possible. Forms should be designed so that the casual or occasional computer would not become lost in endeavoring to carry out intricate or involved computations on the keyboard of the machine—the steady or experienced computer will involuntarily take the short cuts anyway, whether the form calls for intermediate results or not. One of the most noticeable traits of computers is "going stale" on the computing forms after having been diverted to other drafting or computing work for occasional periods of a few weeks or so. In such cases the presence of ample labels and "mile-posts" in the computing form is most helpful.

From an administrative point of view, recognition must be given the fact that the majority of computers are recruited either from lists of applicants, often scantily qualified in both mathematics and calculating machine operation, or from chainman-rodman ranks during periods of inclement weather. Thus, computing forms should possess an essence of simplicity conducive to short training periods, and at the same time offer the necessary means of checking, mechanically, as the solution is being "cranked through." One of the worthy features of the Bureau of Reclamation three-point solution is its elimination of an inverse solution between the main scheme stations; often these values are not available from the geodetic reduction, particularly in such cases as water towers, spires, and other points originally located by second-order as intersection stations. Although the possible use of the check-position cut was mentioned in the discussion of the three-point solution, and further laudably mentioned in the discusser's conclusions, the Macleish forms have not provided for incorporating the "check-position" cut in each solution—a feature which the writer emphasizes as of utmost importance in any cadastral surveying technique which departs from the conventional ground methods.

Aside from the matter of computing forms, Mr. Macleish questions the justification for using tenths of seconds. The writer's decision to use tenths of seconds throughout was made, not as an attempt to imply a higher degree of accuracy than was actually attained, but rather to unify all computation work by removing from the computer's mind unnecessary mental "traffic signals" through the several steps of the computation. What actual justification there might be for this practise would doubtless be limited to the following:

On long lines of observations and weak fixes or intersections, the field-observed directions might actually be accurate within 0.5 sec. In such cases it seems quite worth while to compute the point with the use of tenths of seconds rather than round off the directions to the nearest whole second and risk distorting an angle from 0.5 to, say, 1.5 sec. If, then, it is worth while to compute an occasional point with tenths of seconds, it is logically economical to compute all third-order work with tenths of seconds, for unless one is using tables of functions listed for every whole second, the extra time required to interpolate the function of tenths of seconds on the machine is negligibly greater than the time required to interpolate to whole seconds. Moreover, computers work most efficiently if they handle the same number of decimal places in seconds, distances, etc., in all the operations throughout the day. For example, in occasionally carrying computations to tenths of a foot instead of to hundredths of a foot it was disclosed that in the long run there was more time lost than gained, because the computer had to stop to think that he must not put down the hundredths in his computations.

Mr. Macleish has commented regarding the requisite of a ten-bank computing machine for the Bureau of Reclamation intersection computation form.

Although this was never a matter of concern inasmuch as it seems to be the policy of the Bureau to purchase only ten-bank machines, the eight-bank machine could nevertheless have been used in all cases with but little inconvenience. To use an eight-bank machine the first two figures of the X co-ordinate would be omitted in forming Equation (1). After adding the two equations the X-value thus obtained by dividing would then be, say, 55 948.40 to which would be added the figures previously dropped to obtain the true X co-ordinate, 2 655 948.40. The large cotangents of lines bearing approximately north and south are no trouble because the rate of change of X is so small. On these very nearly north-south lines one can almost estimate the X co-ordinate before looking up the cotangent; to obtain the true X-value of the station the computer simply feeds the machine the customary number of significant figures, nine or ten if using a ten-bank machine, seven or eight if using an eight-bank machine, and the customary accuracy results in the answer. The only hazard of large cotangents is that an inexperienced computer may compute the Y-value of the intersection station by substituting the X-value in the equation having the large cotangent. However, if he immediately checks his Y (as he always should) by substituting X in the other of the pair of equations, he finds the Y-value does not check very closely and thereafter knows better than to expect north-south lines to offer accurate Y-values. Mr. Macleish has spent much careful thought and analysis on the subject, and is to be complimented for the masterly manner in which he investigated the subject and presented his discussion.

It is indeed gratifying that the discussers are all engineers who are well acquainted with this field of work, and the writer feels that an impressive assurance has been given a method which has as its objective an economical procedure for a controlled, permanently marked, and recorded land-acquisition survey.

Paper No. 2086

DEVELOPMENT OF THE COLORADO RIVER IN THE UPPER BASIN

By Thomas C. Adams,[1] M. Am. Soc. C. E.

With Discussion by Messrs. C. C. Elder, and Thomas C. Adams.

Synopsis

In a general way, this paper treats the past and prospective use of water of the Colorado River and its tributaries in the upper basin above Lee's Ferry, Ariz. Descriptions are given on the topographic, industrial, and agricultural features connected with the basin and the effect of the Colorado River Compact and the Boulder Canyon Project Act on the use of water. Water supply for the upper basin, after agreements between the States concerned are satisfied, is shown to be somewhat less than had been anticipated by some.

Conditions favoring and limiting future extension of irrigation in the upper basin are described. Additional irrigation projects of the normal type will be built; other projects, primarily to aid the livestock industry of the region by the irrigation of meadows and feed crops, are held to be desirable; and, the large diversion projects conveying water outside the water-shed of the Colorado River for irrigation, power, industrial, and municipal purposes are shown to be highly important in the general plan of upper-basin development. The hydro-power resources, the rôle to be taken by power generation in water development, and the relations between the use of water of the upper basin and the social, economic, and industrial growth of the basin and near-by regions, are discussed. The paper includes an appendix containing data on the irrigable areas of the upper basin and an analysis of the flow of the Colorado River at Lee's Ferry (where division is made between upper and lower basins) since the signing of the Compact, which is believed particularly significant as it handles flow during the period of lowest known river flow.

Topography and Industry

Lee's Ferry is situated on the Colorado River of the West, in Arizona, immediately below the State line between Utah and Arizona (see Fig. 1). The

---

Note.—Presented at the meeting of the Irrigation Div., Salt Lake City, Utah, July 21, 1938, and published in September, 1939, *Proceedings*.

[1] Associate Prof., Civ. Eng., Univ. of Utah, Salt Lake City, Utah.

area drained by this river and its tributaries up stream from the old ferry site is known as the upper basin. It is an extensive shallow basin "funnelling" to its river outlet, rimmed on the east by the crest of the Rocky Mountain Cordilleran and to the west by the somewhat lower crests of the Wasatch Mountains and those other mountains and high plateaus to the north and south. The basin comprises the highest area of so large proportions in the United States. It includes within its water-shed a varied topography of well-watered mountain heights, delightfully green mountain valleys and stream canyons, flat mesas, barren deserts, and profound box canyons. Adjacent to the basin, and just over the mountain crests on both the east and the west sides, are areas somewhat lower in elevation, having rich soil and more equable climate, and containing some of the most populous agricultural and industrial areas, of the western interior.

Localities within the upper basin and near-by are noted for their mineral wealth, and the region will continue for a long time to produce large quantities of non-ferrous and ferrous metals, coal, oil, natural gas, and a large variety of other non-metallic and rare minerals. The principal industries are stock raising, farming, mining and treating minerals, and the distribution of commodities produced elsewhere. The upper basin of the Colorado River is 104 000 sq miles in area and lies partly in each of the States of Utah, Colorado, Wyoming, and New Mexico. It is one twenty-ninth the area of continental United States and hence nearly twice the area of an average State. It is well supplied with railroads and highways but is only sparsely populated.

The mountain rims of the upper basin and other mountains lying within it receive a high rate of precipitation and from this small part of its area flows nearly 80% of the entire water supply of the Colorado River Basin, one thirteenth of the area of the United States. These mountains support no farming or agriculture other than open grazing because of the extremely short growing season. All other lands in the basin, with the exception of limited acreages of "dry-farm" wheat fields, are deficient in rainfall and must be irrigated to produce crops. Much of the area of the upper basin lies at the foot of the mountains and is itself high in elevation (more than 6 000 ft). It comprises broad plains, valleys, and mesas, the growing season of which is short. Agriculture is limited largely to the raising of livestock and the irrigation of feed crops. Lower parts of the upper basin, in southeastern Utah and adjacent parts of Colorado, have suffered deep erosion in recent geologic times and are a jumble of box canyons and desert mesas and plateaus which, in some places, are almost devoid of soil. Irrigated lands are limited to favorably disposed positions in stream valleys.

IRRIGATION DEVELOPMENT

Irrigation development of the upper basin began early (William H. Ashley[3] and his trappers entered the Uinta Basin in 1824) and has proceeded in the manner typical of western irrigation. At the beginning small ditches were constructed by individuals and associations of individuals. These were fol-

lowed by larger projects built by companies and, co-operatively, by users; and, finally, it was followed by those constructed by the United States Bureau of Reclamation under increasingly lenient financial terms. Development has proceeded steadily, but in recent decades developers have encountered the need for more thorough planning of projected irrigation works, the necessity of dealing with projects of larger scale and complication, of being satisfied with serving land less advantageously situated with respect to the water supplies, and using dams sites of higher unit cost. Furthermore, as time has progressed, there has come a realization that the few million acre-feet of water coursing down the streams of the basin are a vital economic factor of the region and, because of their meagerness, must be carefully conserved.

Agricultural production of the upper basin is generally not competitive with that elsewhere in the United States. It is small in comparison—much of it is consumed locally, and the remainder is mainly supplementary to national agriculture as represented by the livestock and the specialized irrigated crops.

Before 1922 a demand for the use of more water of the Colorado River in the lower basin and for the construction of a large dam and reservoir to permit this use and to provide flood protection for the irrigated valleys of the Colorado Delta and electricity and water for Los Angeles, Calif., led to negotiations between representatives of all States of the basin which culminated in the Colorado River Compact signed in November, 1922. The Compact was supplemented and approved conditionally by the Boulder Canyon Project Act of December, 1928. Under the terms of the Act the Compact became effective as regards all States concerned, except Arizona (which refused to ratify the compact) in June, 1929, six months after the Act was signed. California was required, by the Act, to accept the provision that no more than 4 400 000 acre-ft, plus one-half the surplus which might later be allotted to the lower basin, would be consumed in the State. The Compact reserved for the upper basin consumptive use of 7 500 000 acre-ft of water per yr but subjected this to an obligation which takes precedence; namely, that in any 10-yr period a total of 75 000 000 acre-ft of water are to be permitted to flow from the upper basin past Lee's Ferry gaging station for the benefit of the lower basin. Further provisions are that no water "which cannot reasonably be applied to domestic and agricultural uses" is to be withheld in the upper basin and that any water which may be granted to Mexico shall be supplied first from the surplus flow of the river in excess of the amounts allotted to the upper and lower basins; or, in the event that this surplus is insufficient to meet the Mexican grant, the deficiency is to be supplied half from each of the upper and lower basin allotments. The Compact is a comparatively simple document intended to permit lower-basin developments to proceed and to preserve sufficient water for the upper basin developments which are intended to follow in due time. It "sets aside" questions of priority of appropriation as between the upper and lower basins. Assuming good faith by all parties, the Compact may well accomplish its objects and be beneficial to every one. It is an equitable document.

Under the Boulder Canyon Project Act no work was undertaken; nor was any immediate benefit in the nature of construction intended, to the upper basin, with the exception of a moderate appropriation for studies of proposed developments throughout the entire basin. The Act set aside receipts from the use of works to be constructed under it after repayment to the Government of all costs of these is completed, in a fund which presumably would be devoted, at the direction of Congress, to further construction in the basin and partly in the upper basin. Through the construction of the storage reservoir at Hoover Dam (Boulder Dam in Fig. 1), the Act was intended to remove the possibility that litigation in support of prior appropriations made of Colorado River water in the lower basin would interfere with, or prevent, further developments in the upper basin.

APPRAISAL OF PAST EXPERIENCE

Sixteen years have now (1939) elapsed since the signing of the Compact and ten years since the passage of the Boulder Canyon Project Act; and it is of importance to upper-basin development to know what light and fruition intervening years have brought to the terms and intentions of these notable documents. Since 1922 many more discharge measurements of the Colorado River have been made and earlier discharge records corrected. Furthermore, the most severe drought period known has occurred, from which recovery is being made only during the present year. A review of the discharge of the Colorado River at Lee's Ferry since 1922 discloses an average measured discharge of 12 750 000 acre-ft per yr. To this may be added an average estimated upper-basin depletion of 2 180 000 acre-ft per yr, totaling 14 930 000 acre-ft per yr, which is an amount on the average for the seventeen years, 1922–1939, slightly less than sufficient to meet the Compact provision of 7 500 000 acre-ft per yr to each of the two divisions of the river basin. These values may be compared with an average, all-time, reconstructed flow of about 17 000 000 acre-ft per yr believed to be the yield of the river system above Lee's Ferry when the Compact was drawn. The low average discharge since 1922 would have the effect of reducing the all-time average to date by a small amount. For the last ten years of record (1929–1939), the values corresponding to those given are 11 720 000, 2 110 000, and 13 830 000 acre-ft per yr, respectively. To obtain the total quantity of water available for use from the Colorado River and its tributaries in both the upper and lower basins, after the terms of the Compact are applied, adjustments for gains and losses in the lower river must be made and a deduction taken for water granted to Mexico. No statement can be given of water that may be granted to Mexico. Only that title to water there established by treaty need be recognized and no treaty exists. The present use of water from the Colorado River in Mexico is about 1 000 000 acre-ft per yr.

A further study of the Lee's Ferry discharge shows that at the end of the water year, September 30, 1937, there would have been a deficiency in the 10-yr cumulative amounts (which the Compact specifies must be not less than 75 000 000 acre-ft for any 10-yr period) of 5.5 million acre-ft if use of water in the upper basin had reached the proportions requiring 7 500 000 acre-ft per yr in a year of normal stream discharge (which amount would be appropriately less in drought years) and in the absence of large, long-carry-over storage in the upper basin available to supplement stream discharge. Furthermore, even if the discharge of the river increases and remains above average during the ensuing years beginning with 1939, the deficiency in the 10-yr cumulative discharge will increase to perhaps the end of the water year of 1939 when it will possibly be 10 000 000 acre-ft. It is not likely that this 10-yr amount would again reach the 75 000 000 limit until well into the 1940's, barring continuously and phenomenally high discharge of the river.

Other studies of discharge show that in the ten years just passed an average of 5 800 000 acre-ft per yr would be available for upper-basin use from direct stream flow had the upper basin been using all available to it under the Compact, with adherence to the 10-yr cumulative provision included but without being obliged to share in an allowance of water to Mexico (see Column (12), Table 2 in the Appendix). Considerable storage would be required on upper tributaries of the river to equalize this average flow, throughout the 10-yr period, in a manner acceptable for upper-basin use. Water available to the upper basin under the conditions specified could be increased appreciably if large carry-over storage on the tributaries or the main river in the upper basin was available to assist in supplying 10-yr cumulative demands of the lower basin at Lee's Ferry.

These studies also show that an average of 6 700 000 acre-ft per yr during the ten years, 1929–1939, would be available from direct stream flow at the outlet of Hoover Dam under the foregoing conditions (see Column (14), Table 2). The equalization of this flow could take place in Lake Mead. This flow, plus allowable cumulative depletion of Lake Mead throughout the drought period, would constitute water available for lower-basin use on the main river plus one-half of any water granted to Mexico. A study has been made of the depletion of Lake Mead governed by the presumption that all requirements of the lower river will be met by a discharge of 7.5 million acre-ft per yr of water from Hoover Dam. The result is a maximum cumulative depletion of 20.0 million acre-ft in 1936 (see Column (16), Table 2).

Records are insufficient to show how frequently drought periods such as the one of the ten years, 1929–1939, will be repeated. Indications are that four droughts of considerable severity have been experienced in the past hundred years.

Construction of projects in the lower basin, provided for by the Boulder Canyon Project Act, has progressed rapidly and major items are (in 1939) substantially completed. Other, smaller, related projects have been authorized for the lower basin. The following has particular importance: Projects or divisions of projects in the lower basin which will draw their water supply from the main Colorado River are those (a) which are now (1939) fully planned; (b) for which money has been provided at least in part; and (c) upon which construction has begun or is about to begin. When 90% developed, they will require (together with projects at present (1939) operating) an annual quantity of water fully equal to the average available during the ten years, 1929–1939, to the lower basin under the terms of the Colorado River Compact from the flow of the river. The eventual needs of these projects are estimated herein at 6 200 000 acre-ft per yr, requiring the delivery at Hoover Dam of 7 000 000 acre-ft per yr with the average direct stream flow available at the outlet of the dam of 6 700 000 acre-ft per yr. If this demand is increased and particularly if it is burdened further with an additional grant of water for Mexican lands, Lake Mead will be seriously depleted in a series of drought years such as those through which the United States has just passed and under the conditions of river development which have been assumed.

However, a number of years will elapse before the lower-basin projects will need their full quantity of water. This time has been advanced due to conditions growing out of the years of depression through which the nation has been passing and by failure to realize earlier anticipations.

Appraisal of Future Trends

The consequences upon future use of water in the upper basin of the Compact, Boulder Dam Act, deficient stream flow, and accomplished and planned construction on the river may be briefly summarized as follows: (1) Early estimates of surplus, unallotted water are shown to be in error; (2) any increase in the use of water above that planned, and for which construction of works has begun in the lower basin, will require the appropriation of water which it has been presumed has been reserved for upper-basin use; (3) the small, future, financial aid that upper-basin development expected to receive from payments made to the Boulder Dam Fund by users of power and water is of doubtful maturity; (4) large storage volume upon the upper tributaries will be desirable for river regulation before final development is attained; (5) for a number of years large quantities of surplus water will flow into or through Mexico and will be available in part for use there with the possibility (according to the views of some) that use there will follow and finally that rights will be granted by treaty, with resulting ultimate detriment to the upper basin and perhaps to the lower basin. In pursuance of this condition an amicable agreement with Mexico should be made, if possible, protecting the water for United States use; or, failing this, a system for regulating the river should be adopted which will make further irrigation development in Mexico impossible through the resulting river regimen. The last may require the construction of additional reservoirs or, as a temporary expedient, the curtailment of some power development at Hoover Dam; but it is believed entirely feasible.

About 1 500 000 acres of land are now (1939) irrigated in the upper basin of the Colorado River. It is believed that this land consumes about 1.5 acre-ft per acre of water in years of plentiful water supply, or a total of 2 250 000 acre-ft. About 130 000 additional acre-ft have been diverted each normal year from the basin. Estimates of the additional area which, eventually, can be irrigated have been made and total about 2 500 000 acres; but these estimates are open to question, and studies are in progress, principally by the U. S. Bureau of Reclamation, to define, more accurately, the arable, and perhaps potentially irrigable, acreage. The results of recent surveys for the area drained by the Upper Colorado River in the State of Colorado (excluding the tributaries of the Gunnison and Dolores Rivers) have been made public and may be compared with an earlier estimate of potentially irrigable area in this basin of 290 000 acres. The recent survey gives the arable land in this same basin as 122 830 acres, less than half of the 290 000 acres (see comment on Table 3, in the Appendix). It is said, however, that the 122 830-acre estimate intentionally omits some land irrigable for meadow. Perhaps a similar reduction will be indicated for other subdivisions of the upper basin; but even these recent, more careful, surveys do not vouch for the general economy and feasibility of irrigating all the arable area which they disclose, nor for the adequacy of the water supply available to each area. Therefore, it remains uncertain how much of the 2 500 000 acres of upper-basin land, reported earlier as suitable for irrigation, will be irrigated.

By definition, the Colorado River Compact makes any area supplied with water from the river or its tributaries a part of the river basin even if it may lie without the water-shed (although this tacitly applies only to the signatory States and does not authorize nor encourage diversion of Colorado River basin water outside of States of the basin). The makers of the Compact fully intended that water of the river system should be used either within or without the basin as desirability later dictated. However, diversion of water from the upper basin for use on adjoining areas is now assuming an importance greater than was contemplated. The Colorado-Big Thompson Project is an object lesson to those whose engineering vision is restricted. A few years ago, this diversion (which will cost $44 000 000) was seriously considered only by a few of the most comprehending engineers. Others deemed the possibility of the undertaking as remote. The soundness of great diversions from the basin is due to the presence of highly developed agricultural, urban, and industrial areas just outside the basin which, although separated by mountain rims from the basin, are lower in elevation than much of the basin area. Hence, they have longer growing seasons and also possess abundant, highly productive soils, opportunities for the consumption of large quantities of electric power, and in general offer situations in which water supply has the best opportunity to stimulate an advanced economic and social development.

On the east side of the upper basin, in Colorado, twelve trans-mountain diversions have been operated for a number of years. The most important of these is the Grand River Ditch crossing the continental divide west of Ft. Collins, Colo. Only one is a tunnel, the Busk-Ivanhoe, west of Leadville, Colo., which makes opportune use of an abandoned railroad tunnel, shared with a highway. These diversions are said to have a normal aggregate capacity of 46 000 acre-ft per yr. The Moffat Water Tunnel Diversion was placed in operation in 1937. This structure is for the benefit of the City of Denver, Colo., and can divert 80 000 acre-ft per yr. The Jones Pass tunnel diversion, at the head of Clear Creek west of Idaho Springs, Colo., for the City of Denver has a capacity of 20 000 acre-ft per yr. This water is used to boost the low-water discharge of the South Platte River in the vicinity of Denver to avoid excessive pollution of this stream by the effluent from the Denver Sewage Treatment Works. After this use, it serves for irrigation and, when not required to increase the discharge of the river, may be turned into the Denver municipal supply. A notable tunnel trans-mountain diversion, constructed in 1938, is the Independence Pass (or Twin Lakes) which brings 48 000 acre-ft per yr into the head-waters of Arkansas River southwest of Leadville. The most pretentious diversion project that has reached the construction stage is the aforementioned Big Thompson project. It has many features and will divert 300 000 acre-ft of water beneath Rocky Mountain National Park for wide-spread benefit of the irrigated area of north-central Colorado. Power obtained from the falling water on the east side of the mountains is an important factor in the usefulness of the project.

Besides the trans-mountain diversions which have been noted, more than 17 others situated throughout the length of the crest of the Rocky Mountains in Colorado and dipping into New Mexico have been studied. Several studies have included field surveys and hydrography. Some of the projects are large.

Along the west rim of the upper basin, in Utah, nine diversions across the water-shed have been operated for several years. Much more important than the others is the Strawberry Tunnel which transports about 50 000 to 70 000 acre-ft per yr into the Utah Valley. In 1938, two, 1-mile diversion tunnels were built east of Spring City and Mount Pleasant, Utah, to transport 4 000 acre-ft each into the San Pitch Valley. These supersede two of the small earlier diversions. The Deer Creek project includes, as one of its features, a 5.5-mile tunnel to divert 32 000 acre-ft from the Duchesne River to the head of the Provo River, 35 miles east of Park City, Utah. More than eight other projects for diverting water from the upper basin to valleys lying to the west have been studied. In one of the most important of these it is planned to divert water from the Green River north of the Uinta Mountains to the Bear River, Wyoming. Investigations of two alternate plans including field surveys have been made by Mr. Ralf R. Woolley of the U. S. Geological Survey. A project of even greater magnitude has been studied by Mr. Kenneth Borg. This project would transport water from the Green River south of the Uinta Mountains and deliver it for use in the Salt Lake and adjacent valleys.

It is likely that development within the water-shed of the upper basin will progress in the form of a number of projects of moderate or small size. A considerable number of these have been given study. Localities exist within the upper basin where special crops and fruits grow luxuriantly. The produce is of such high quality that it is possible to overcome the handicap of remoteness and command a premium for it on national markets. Localities of this nature deserve expansion. Other localities, particularly the stream valleys at high elevations situated close to mountain and high plateau livestock ranges, support a productive livestock industry. It is said about half the feed for livestock in these areas comes from the ranges and half from cultivated fields. Western livestock raising is a highly specialized industry conducted mainly by men of great skill who have spent their lives in this occupation. When properly organized and managed, individual units may be very profitable; and extension of irrigation for the benefit of this industry, even at a cost that seems somewhat out of proportion to the low current prices for hay crops, is justified. Since 1936 the open range has been under close regulation; its use has been curtailed and made permissive in order to preserve its feeding capacity. Furthermore, use of the range has been made conditional upon the possession of commensurable property from which feed may be produced to supplement, to an extent more than required by natural conditions heretofore, the feed produced by the range. In this manner additional irrigated land for the production of livestock feed is assuming a new importance.

Developed water power in the upper basin of the Colorado River totals about 50 000 installed horsepower; and nearly all of it is along the Upper Colorado River in the State of Colorado where power-plants are within transmission distance of the Denver area. It is estimated that the upper basin can produce 2 000 000 primary horsepower with a regulated stream flow. Power sites on the Green River and main channel of the Colorado River, in their courses between Green River, Wyoming, and Lee's Ferry, are capable of producing the bulk of this output. Several gigantic dams would be required and the power would necessarily be made available in large blocks, with large initial investments being required. The power that can be developed will be lessened by future up-stream depletion due to irrigation development and the diversion of water from the basin. Proposals to place long reaches of the river and adjoining lands in national parks constitute a threat to the development for power and perhaps other purposes of the Green and Colorado rivers, in Utah. The necessity, or desirability, of making park reservations of these lands may be seriously questioned. Although they constitute scenic features of great importance and magnitude, and although money should be spent to provide means of access and travel, the natural scenery is not of a nature that it can be marred appreciably by such unrestricted human habitation and use as it is likely to undergo. Rather the few ranches, prospectors and nomad Indians who inhabit the country, add much to its picturesqueness. Dams and conduits that may be built will be only tiny spots in a vast wilderness of canyons and plateaus, largely of bare sandstone and shale. The few individual features requiring protection can be individually reserved without laying the "heavy hand" of park reservation over the entire area.

Conclusions

Conditions which will justify the development of the large power sites are unforeseen at present. Two possibilities are the construction of major dams for river control with the generation of power as a by-product, for sale at a price so low as to attract, to the vicinity, industries in which the cost of power bulks large; or an unforeseen technological development favorable to the development of power in this region.

This paper shows the development of the Colorado River in the upper basin to be varied and complex. Units in this development may be approximately grouped into: (1) Normal irrigation enterprises for assorted farming products; (2) irrigation of lands to produce livestock feed and meadow; and (3) the diversion projects. This classification is mainly an economic one.

Many of the undertakings for using water in recent years (and, most likely, many of those to be undertaken in the future) will furnish additional water to projects already operating. For some operating projects stored water is needed for late-season use when stream flow is normally low. Other operating projects exhibit the habits, not uncommonly displayed by western irrigation projects, of having a water supply that was initially over-estimated and hence unreliable, or having a canal system extended to serve lands for which no adequate supply of water is available; and under these conditions a supplementary supply of water is needed. In general, projects for supplying supplementary water where this is needed are regarded as particularly desirable because a small increment of investment commonly produces a relatively large increment of utility or return.

The proposed large diversions from the basin are especially complex and are the objects of particular engineering interest. Each includes a number of features such as: Collecting works; dams for diversion; storage reservoirs (for (*a*) water diverted, (*b*) water to supply deficiencies in lower reaches of the stream from which the diversion is made, and (*c*) to redistribute water near the points of use); pumping plants; electric generating stations; transmission lines; long tunnels; and, the more usual conduits and water control structures. The variety of purposes served by these projects includes irrigation supply, water for industrial and varied municipal purposes, improvement of recreational features, and the generation of power. With some projects should be included the functions of drainage, protection of land from torrential floods, and recovery of seepage, waste and return flow from low streams, drains or lakes. Some may serve the supplemental purpose of transporting power in the form of flowing water at a high elevation to a point where the generation of electricity can occur closer to markets and where greater power, by virtue of higher head, can be recovered.

It is an accepted fact that power generation is to play an important rôle in water development in the West. This is true in the upper basin of the Colorado River both for the projects within the basin and for the large diversions from the basin. Power generating stations, transmission lines, and pumps, free the energy gradient of the combined stream from many topographic limitations which would have to be met if water conduits alone were used. Increased efficiencies of electrical and hydraulic equipment now available and their lower cost and greater reliability—all coupled with the fact that a power system created as a part of water development and built primarily to serve this purpose, often does not need to meet separate development costs or the service requirements of systems built for other purposes—increase the usefulness of such power adjuncts to water projects. Then too some water development projects provide surplus power to sell at a profit to pay part of the cost of water development construction. However, if this is to continue to be an effective method of financing water projects, those interested in them must protect the power market and discourage abortive attempts to obtain cheap power through outside subsidy which, in turn, reduce or destroy the possibility of power development subsidizing water development.

The conviction is held by many that the water of the Colorado River System in the upper basin should be used in ways and places that will, most effectively, build communities with a broad industrial base, including not only agriculture but the winning and fabrication of mineral products and use of other industrial resources of the region. To the extent that this can be accomplished will come wide-spread advantages not only for residents of the basin and adjoining areas but for all areas within trading distance. This area may be indefinite in extent but it includes, more especially, the Pacific Coast and the Great Plains States. Communities dependent upon agriculture, supplemented by other industrial production, appear to have a more promising future in the inter-mountain west than communities dependent upon agriculture alone. This general thesis is further justification for the use of available water supplies to expand communities already established and experiencing healthy growth as a result of a combination of good agricultural conditions surrounding them, favorable position as trade centers, and possession of resources and facilities for other forms of industrial development. It is also a further justification for the great exportations of water from the basin which are being undertaken and proposed, and for the relatively high cost of these projects and the initial financial subsidization they need.

The general planning of the development of the Colorado River and its tributaries in the upper basin will continue. Such general plans are subject to drastic modification as new conditions develop and new information is available. Some past results are readily accessible in *Water Supply Papers* of the U. S. Geological Survey and various reports prepared by the U. S. Bureau of Reclamation and agencies of the States concerned. There remains, as distinct from general planning, a vast mass of engineering planning, of a detailed nature: (*a*) to unravel the hydrographic and other engineering complexities of individual projects; (*b*) to devise better and more economical combinations of their features; and (*c*) in short, by engineering ingenuity, to bring individual projects within the limits of an assured feasibility. The U. S. Bureau of Reclamation is undertaking a part of this heavy burden, successfully, and representatives of States and areas which are to participate in the benefits should assume another part of it both to bring more resources to the study and to insure realization of the opportunities which are within their grasp.

ACKNOWLEDGMENT

Fig. 1 has been reproduced from Drainage Basin Studies of the Water Resources Branch of the National Resources Committee.

APPENDIX

SUPPORTING DATA

FUTURE WATER SUPPLY

Table 1 contains an estimate of the future water supply to be drawn from the main channel of the Colorado River, below Lee's Ferry.

TABLE 1.—APPROXIMATE ESTIMATE OF FUTURE WATER SUPPLY TO BE DRAWN FROM THE MAIN COLORADO RIVER, DOWN STREAM FROM LEE'S FERRY

Item	Development (1)	Acres irrigated since 1937 (2)	Water diverted in recent years, in acre-feet (3)	Future irrigated area, in acres (4)	Future demand for water, in acre-feet per year (5)
1	Colorado Indian Reservation	7 500	....	100 000	270 000
2	Colorado River, Los Angeles Aqueduct	....	....	....	1 000 000
	Palo Verde Irrigation District:				
3	Developed by present canal system	23 000	225 000	75 000	....
4	By total anticipated development	....	....	115 000	200 000
	Gila Project:				
5	First unit, east of Yuma, Ariz.	....	....	150 000	405 000
6	Completed project	....	....	2 900 000	....
7	Yuma Project	60 000	450 000	80 000	325 000
8	Imperial and Coachella valleys	450 000	3 000 000	1 000 000	4 000 000
9	Total	....	....	....	6 200 000
10	Mexico	....	850 000	....	....
11	Hoover Dam losses	....	....	....	500 000
12	Net river losses below Hoover Dam	....	....	....	600 000
13	Sluicing and incidental loss at, and below, Imperial Dam	....	....	....	200 000
14	Power and irrigation losses, Lee's Ferry to Hoover Dam	....	....	....	300 000
	Gain, Lee's Ferry to Hoover Dam:				
15	Minimum	....	....	....	200 000
16	Maximum	....	....	....	700 000

Heading.—In the preparation of values of estimated future demand for water, attention has been given mainly, in the case of irrigation projects, to the indications afforded by physical features of the area served and of the construction completed, under way, or authorized. Thus constructed canal capacities and present experience with irrigation have been given more weight in arriving at values than general agreements or understandings regarding the distribution of water. But in all cases the figures adopted are intended to be conservative in not overstating the quantities.

Those familiar with Colorado River agreements may note some discrepancies between stated future demands for water and certain stipulations that have been made.

The following notes refer to corresponding items and column numbers in that table:

Item 8, Column (3).—Includes losses of the main canal through Mexico

Item 10, Column (3).—This quantity is water measured to irrigators in Mexico and does not include the transmission losses that will be incurred through the continuation of the Mexican Canal in operation after water for the Imperial Valley is drawn through the All-American Canal.

Items 3 and 4, Column (4).—The smaller acreage noted lies within the valley and is likely to be developed by the present canal system. The larger acreage includes good land on the mesa to the west of the Palo Verde Valley, which may be irrigated with a moderate pump lift.

Items 5 and 6, Column (4).—The smaller acreage is for the first unit of the Gila Project lying east of Yuma. It is reasonable to suppose that, when completed, this unit will be developed to a moderate degree within a few years. The entire Gila Project includes about 500 000 acres maximum; but other proposals have been made for the irrigation of the lands of the Gila River Basin of Arizona from the Colorado River and the large estimate given by Item 6 is perhaps the greatest aggregate acreage of these proposals.

Item 7, Column (3).—This is the quantity of water diverted for irrigation and excludes water diverted for power and other uses.

Discussion of Column (5), Table 1

Item 1, Column 5.—This estimate is based on 90 000 acres at 3.0 acre-ft per acre. Return flow from the Indian Reservation will re-enter the Colorado River for use below. A contract has recently been let for the diversion dam to serve this project.

Item 2.—The capacity of the Colorado River aqueduct is to be 1 640 cu ft per sec or 1 180 000 acre-ft per yr but it is intended to operate at 1 500 cu ft per sec or 1 090 000 acre-ft per yr. The date for the attainment of full operation was set by earlier forecasts at about 1970.

Item 4.—This estimate is based upon 90% of 75 000 acres at 3.0 acre-ft per acre. Return flow from the Palo Verde Irrigation District will re-enter the Colorado River for use lower.

Item 6.—This estimate is based upon 90% of 100 000 acres at 4.5 acre-ft per acre. It is to be noted that this acreage is less than two-thirds the acreage announced for the first unit of the Gila Project. Also return flow from this project will not be available, without pumping, to any United States irrigation undertaking.

Item 7.—This estimate is based upon 90% of 80 000 acres at 4.5 acre-ft per acre. Return flow from this project will be available only for use in Mexico. It is to be noted that the amount of water estimated for this project is less than the amount now being used on the project as indicated by the diversions made to the project less the large quantity of water returned more or less directly to the river after its use for power and maintaining optimum velocities and depths in a portion of the canal system. The present indicated use of water on this project is considerably greater per irrigated acre than the basis of estimates appearing in the foregoing table and this is true of the use of water on other irrigation projects diverting from the lower Colorado River.

Item 8.—This estimate is based upon 90% of 1 000 000 acres at 4.5 acre-ft per acre. The canal considered is the All-American Canal which will supply water to the present Imperial Valley, extensions to this within the Imperial

Irrigation District, to the East and West Mesas adjoining, the Coachella Valley, and possibly to San Diego, Calif., and vicinity, and other areas. The capacity of this canal (beyond Pilot Knob) is 10 000 cu ft per sec or 7 300 000 acre-ft per yr; 4 000 000 acre-ft are 55% of the canal capacity. Considering canal capacity to be 11% greater than the discharge (average) of the maximum month, the ratio of water diverted during the year to the annual canal discharging capacity is nearly 0.60 for the Imperial Canal and Yuma Main Canal (irrigation use only) within recent years.

Item 11.—This item is mainly evaporation. The value stated has been widely used as the evaporation from the reservoir some decades hence when the reservoir has been considerably silted and perhaps somewhat contracted in area. No doubt, the present evaporation is larger than this amount and there is some possibility that it is larger than is generally believed and will be larger in the future than the amount stated (for more information see Column (10), Table 2).

Item 12.—This is mainly evaporation from the river surface, adjacent flood plain, and Parker Reservoir to which is added stream inflow between the points considered. The latter is not great and the result is a rather large net loss as indicated. This net loss has been estimated as much as 200 000 acre-ft per yr greater than is given herein and may be considerably higher when other reservoirs are constructed on the lower river.[3]

Item 13.—It is expected that some loss of water from the Colorado River to the Gulf of California cannot be avoided. It is also considered by some that sluicing down the river of silt removed from All-American Canal water at Imperial Dam will require considerable water. Official estimates of water for incidental losses and sluicing are about twice the value stated in Table 1.

Item 14.—This amount includes allowance for evaporation from reservoirs which in the future are expected to be constructed on the Colorado River between the Hoover Dam and Lee's Ferry and for irrigation development on tributaries entering the river between these same two points. The two most important tributaries are the Little Colorado and the Virgin rivers. Official estimates are more than twice the amount given.

Item 15.—The gain from Lee's Ferry to Hoover Dam Outlet includes the discharge of the Little Colorado River, the Virgin River, and numerous smaller streams and springs. Evaporation from the river must be deducted and this may be from 50 000 to 100 000 acre-ft per yr. The net annual average gain has been variously estimated between the two values given. For reasons explained under Column (10), Table 2, the writer's estimate is near the low value.

DISTRIBUTION OF WATER BETWEEN UPPER AND LOWER BASINS

Table 2[3a] should not be interpreted as indicating how the water of the Colorado River will be distributed when development has reached a maximum, and during a dry period. Rather it is intended to show what restrictions the Colorado River Compact places upon the distribution of the water under these conditions. A modification in compact provisions may eventually appear desirable.

---

[3] The basic data for this estimate are from the Debler (U. S. Bureau of Reclamation) Report of 1934.

[3a] An addendum to Table 2 is included as Table 4 in the closing discussion.

The table was prepared for water years 1922 to 1937 which include the very dry period from 1931 to 1934 with sufficient years before and after to be indicative. There seemed to be no harm in setting forth presumptive data for later years to indicate what results would follow and the table has been extended to include these and derivations from them. It must be kept in mind, however, that all data for 1938 and following years are imaginary. Also it should be noted that the discharges assumed for 1938 and following years are high compared with the averages for periods passed. It is almost trite to state that if these discharges are as high as estimated, the conditions contemplated by the Colorado River Compact would be more quickly restored and less alarm would be warranted over shortages which would occur during such a dry period as centered about 1931 to 1934. If anything, Table 2 is slightly biased in favor of a larger usable water supply than will be realized from the flow of the river under conditions of the years considered. Explanations of the individual columns follow.

TABLE 2.—DISCHARGE OF THE COLORADO RIVER AT LEE'S FERRY, PRESENTING DISTRIBUTION OF WATER BETWEEN UPPER AND LOWER BASINS AS REQUIRED BY THE COLORADO RIVER COMPACT

* All values below line (for 1938 and following years) imaginary.

Column (1).—The water year beginning October 1 of the previous year and ending September 30 of the year given. All data are for water years.

Column (2).—Measured discharge of the Colorado River at Lee's Ferry, in millions of acre-feet for the water year.

Column (3).—Ten-year cumulative discharges of the Colorado River at Lee's Ferry. The discharge for the year in question is added with the discharge for the nine preceding years.

Column (4).—Estimated annual depletion of the Colorado River above Lee's Ferry due to all present uses and diversions. To and including the year 1934, the depletions given were obtained from the Debler Report[3] on the water resources of the Lower Colorado River. This is the most complete and authoritative source of information. The writer has extended these estimates for 1935, 1936, and 1937 using the formula employed by the Bureau of Reclamation. The Debler Report gives values for calendar years but it is believed they are applicable without appreciable error to water years.

Column (5).—Estimated annual depletion in the upper basin of the Colorado River if development had proceeded to the limit imposed by an average use of 7 500 000 acre-ft per yr. Values for 1934 and earlier were obtained from the Debler Report.[3] Those for 1935, 1936, and 1937 were estimated by the writer following the Debler method. It is to be noted that values in this column vary from year to year with the dryness of the season.

Column (6).—Annual discharge remaining at Lee's Ferry after subtracting the values of Column (5) from the sums of the values of Columns (2) and (4). These latter sums are the total yield of the Colorado River and tributaries above Lee's Ferry. The items of Column (6) are amounts which would be available at Lee's Ferry to the lower basin had "full" upper-basin development existed during the time covered by the table, and without consideration for the provision of the Compact which required 75 000 000 acre-ft to flow past Lee's Ferry in any 10-yr period.

Column (7).—Ten-year cumulative sums of values of Column (6). It is these values that the Compact requires shall not be less than 75 000 000 acre-ft. Note that the values are less than the required 75 000 000 acre-ft for 1936 and 1937 and are likely to be less in succeeding years until 1943. The information in this column indicates that development in the upper basin cannot be based reliably upon an average consumption of 7 500 000 acre-ft of water per yr throughout a series of dry years but must be based upon some less amount; and that there is no surplus water available from the Colorado River over and above the allotments made by the Compact to the upper and lower basins.

Column (8).—Measured discharge of the Colorado River at Bright Angel, Ariz. Bright Angel is midway between Lee's Ferry and the Hoover Dam and below the mouth of the Little Colorado River, which supplies the principal inflow between the two points specified.

Column (9).—These are 10-yr cumulative values of the discharge at Bright Angel.

Column (10).—Differences between measured annual discharges at Lee's Ferry and Bright Angel. The net gain in the Colorado River between Lee's

Ferry and Hoover Dam outlet before deducting evaporation from Lake Mead has been taken numerically equal to these differences in later computations.

The smallness of the gain according to this assumption is somewhat surprising particularly as there is a large drainage area between the points considered. The Virgin River discharges from 100 000 to 400 000 acre-ft per yr into Lake Mead, and measurements by E. C. LaRue, M. Am. Soc. C. E., during August and September, 1923, disclose streams discharging an aggregate of 272.3 cu ft per sec into the Colorado River between Bright Angel and Black Canyon. Furthermore, a comparison of river discharge measurements made at Black Canyon and Bright Angel in 1932, 1933, and 1934 shows net river gains between these points of 200 000 to 400 000 acre-ft per yr. These years immediately precede the impounding of water in Lake Mead.

However, comparisons of the discharge of the Colorado River at Bright Angel and the Virgin River at Littlefield, Ariz., with the discharge from Hoover Dam, and accumulated visible storage in Lake Mead since the impounding of water began and during the period while the reservoir has been filling, show a remaining apparent loss of water after making a generous allowance for bank storage and a customary allowance for evaporation associated with Lake Mead, for most months and years. This may be the result of inaccuracies in discharge measurements, errors in the stated volume-stage relation for Lake Mead, too low an estimate of evaporation, temporary or permanent seepage from Lake Mead greater than was expected, or any combination of these factors.

A close study seems to indicate that: There is a very satisfactory consistency in the data which shows that discharge measurements are to be relied upon as being sufficiently accurate; there may be bank storage or seepage greater than estimated (10 ft of depth for the water area); there is a likelihood that the volume and area of the reservoir are greater for a given stage than has been stated heretofore; there is also a likelihood that evaporation is greater than estimated (6 ft of depth per yr) both because unit evaporation is greater and the area of the reservoir is greater; and, the apparent excess loss has ranged from 200 000 acre-ft in 1936 to 800 000 acre-ft in 1938. Inasmuch as part of this apparent loss is likely to prove to be an actual loss (evaporation and seepage other than bank storage)—perhaps of the order of the discharge of the Virgin River into Lake Mead (which is measured and was credited in the computations)—the net gain between Bright Angel and the outlet of Hoover Dam will continue to appear to be zero if the evaporation from Lake Mead is considered the same as before (at normal stages 500 000 acre-ft per yr when the reservoir area is somewhat decreased by silting).

This is an awkward manner of estimating the water resources of the river but appears to give correct results; and, until the volume-stage-area data for Lake Mead are confirmed or corrected, and until more data concerning the hydrology of the reservoir become available, no change in method is justified.

Column (*11*).—Annual quantities by which discharge passing Lee's Ferry would fail to provide a 10-yr cumulative discharge, at this station, of 75 000 000 acre-ft for any 10-yr period and under the conditions contemplated in the preparation of data for Columns (5), (6), and (7)—that is, an upper-basin development based on an average annual use of 7 500 000 acre-ft of water.

The values of Column (11) are obtained by noting the quantities in Column (7); and when these become less than 75 million, taking (in chronological order) differences between adjacent values. It would thus become apparent at the end of water year 1936 that the discharge of that year had been so low that the cumulative discharge for it and the nine preceding years had dropped to 73.2 million acre-ft; but, had the discharge at Lee's Ferry been 1.8 million acre-ft higher than it was assumed to be in Column (7), the cumulative discharge for 1936 and the nine preceding years would have been exactly 75 000 000 acre-ft. The 1.8 is the difference between 73.2 and 75.0.

Column (12).—Water available annually in the upper basin for consumptive use, based upon a development using 7 500 000 acre-ft per average yr except when this must be diminished to sustain the 10-yr cumulative discharge at Lee's Ferry at the 75 000 000 acre-ft specified by the Colorado River Compact. No shortage in the 75 000 000 acre-ft cumulative amount occurred until 1936; but this could not have been known until the end of 1936 and, therefore, the restitution of the shortage made in 1937. Similarly, it is considered that the restitution of the shortage of 1937 would be made in 1938, and so on. The values of Column (12) are obtained by subtracting from the values of Column (5) the values of Column (11) which appear on the lines next above. It is to be noted that the 10-yr-cumulative-amount provision of the Compact, if strictly adhered to, causes the greatest shortages to occur in the upper basin a matter of years after the end of the dry period. The only substantial effect of following this provision would be to hasten the restoration of the level of Lake Mead or other reservoir. The average of values of the column for the years 1931 to 1940, inclusive, is 5.8 million acre-ft.

Column (13).—Annual discharge at Lee's Ferry under the conditions upon which the data in Column (12) are based. Values are obtained by adding to the values of Column (6), the values of Column (11) appearing in the line next above (the sign is not considered). It is to be noted that under the conditions governing, very little water would be contributed to Lake Mead (or other reservoir on the lower river) in 1931 and 1934.

Column (14).—Annual water supply to the lower Colorado River reckoned at the outlet of Hoover Dam. Conditions of Columns (12) and (13) govern. To obtain the values of this column, the river gains of Column (10) are added to the discharges at Lee's Ferry given in Column (12); 0.8 million acre-ft are subtracted therefrom, representing a future depletion of 0.3 million acre-ft per yr between Lee's Ferry and Hoover Dam, and 0.5 million acre-ft, representing the annual loss from Lake Mead. The average of values of the column for 1928 to 1937, inclusive, is 6.7 million acre-ft. For further information on the probable evaporation from Lake Mead and considerations regarding the gain between Lee's Ferry and the outlet of Hoover Dam refer to the explanation of Column (10).

Column (15).—Departures of the cumulative sum of the values of Column (14) from the cumulation of the average for all years, applied successively each year. This is an indication of the storage requirements for equalizing flows of Column (14) for the entire period.

Column (16).—Likely cumulative depletion of Lake Mead during a drought period similar to the one of 1930 to 1937 after the Colorado River is developed in accordance with conditions stated for the data of Columns (12), (13), and (14). In the preparation of Column (16) the assumption is made that the requirements of the lower basin will necessitate the release of 7.5 million acre-ft per yr from Hoover Dam lake. This will include half of a possible concession to Mexican lands, the other half of which would move through the reservoir, and would be an additional release; but it is not considered in the present calculations because it would be from upper-basin allotments.

The available water from direct stream flow for lower-basin use as given in Column (14) is sufficient to supply the demand of 7.5 million acre-ft per yr without considerable depletion of Lake Mead until the end of the water year 1929; and the reservoir may be considered full at the termination of the spring flood of that year. A start therefore is made in 1930. This year is credited with flow available for the year and from this is deducted 4.0 million acre-ft representing the depletion of the reservoir for power and irrigation during the late summer and fall of 1929 and the spill required to obtain flood-storage volume before the expected spring flood of 1930; then 7.5 million acre-ft, representing the draft for 1930, is deducted. The item in Column (16) then is depletion of the reservoir at the end of the water year. For each subsequent year a credit is made for the flow available, and a deduction of 7.5 million acre-ft is made. This assumes that no spill, waste, or exclusively power use of water will be permitted under drought conditions.

The sum of the following quantities (each in million acre-ft) is 7.5 million acre-ft: Consumptive use by projects in the lower basin whose construction has begun, 6.2; channel losses between Hoover Dam and Yuma, 0.6; waste at Imperial Canal not recoverable in Mexico, 0.2; and, concession to Mexico, 0.5.

Such a drought coming several decades from now, when full development can be expected, would find Lake Mead partly silted. Perhaps its present capacity of 30 million acre-ft would be reduced to 25 million acre-ft. A depletion of 20 million acre-ft would leave 5 million acre-ft in the reservoir, with a head of 293 ft available at the power plant. This is a little more than half the normal head.

DISTRIBUTION OF IRRIGATED, IRRIGABLE AND ARABLE LAND

In Table 3, the data in Columns (2), (3) and (4) were presented by Daniel W. Mead, Past-President and Hon. M. Am. Soc. C. E., in 1929.[4] They are mainly census data and estimates that were available to the Colorado River Board. The data in Columns (5), (6), and (7) were compiled by the engineering staff of the U. S. Bureau of Reclamation under the direction of Frank E. Weymouth, Hon. M. Am. Soc. C. E. They are from a variety of sources including the U. S. Census Bureau.

The two sets of data are not strictly comparable for individual basins because divisions of the basins adopted are not the same; but they should be comparable for the entire upper basin (see Item 5, Table 3).

---

[4] "The Colorado River and Its Development," by D. W. Mead, *Journal*, Western Soc. of Engrs., July, 1929.

Data for arable lands in the basin of the Upper Colorado River have been cited in a report of the Bureau of Reclamation on the Colorado-Big Thompson Project. This report and the surveys of arable land within this basin were made under the immediate supervision of Porter J. Preston, M. Am. Soc. C. E.

TABLE 3.—ESTIMATES OF IRRIGATED, IRRIGABLE, OR ARABLE LANDS IN THE BASIN OF THE COLORADO RIVER ABOVE LEE'S FERRY, IN ACRES

Item	Basin of the:	D. W. MEAD			F. E. WEYMOUTH		
		Irrigated in 1920	Additional irrigable or arable	Total	Irrigated in 1922	Additional irrigable or arable	Total
	(1)	(2)	(3)	(4)	(5)	(6)	(7)
1	Green River	643 000	1 212 000	1 855 000	532 000	1 067 000	1 599 000
2	Upper Colorado River	542 000	412 000	954 000	588 000	890 000	1 478 000
3	San Juan River	157 000	729 000	886 000	156 000	653 000	809 000
4	Remaining parts of the upper basin	128 000	102 000	230 000	171 000	130 000	301 000
5	Totals	1 470 000	2 455 000	3 925 000	1 447 000	2 740 000	4 187 000

For the basin of the Upper Colorado River in Colorado, excluding the Gunnison and Dolores river basins, comparisons with the Weymouth Report are as follows:

Report	Area, in acres
Porter J. Preston:	
Irrigated about 1935	256 300
Additional irrigable or arable	122 830
Total	379 130
Frank E. Weymouth:	
Irrigated in 1922	245 000
Additional irrigable or arable	290 000
Total	535 000

In the Preston Report the land is classified as arable but not necessarily irrigable from the standpoint of economy or adequacy of local water supply. Some areas which are said to be irrigable for meadow feed for livestock were omitted from the estimate intentionally. The Weymouth data for this basin are directly comparable in regard to the basin limits; but they include irrigated pasture land that was omitted from the Preston Survey.

DISCUSSION

C. C. Elder,[5] M. Am. Soc. C. E. (by letter).—As indicated by the title, the paper includes a comprehensive picture of Upper Colorado River Basin developments and a summary (see Appendix), in readily understood form, of the status of planning and investigations for future projects. The paper's chief value may well be (as was doubtless intended by the author) to broaden the viewpoint of engineers and others interested directly and too narrowly in special projects and localities, but who so often seem "too close to the forest" to see more than a few of "the trees."

For a considerable accomplishment toward this difficult goal, the author deserves much credit; and, as regards the portion of the paper covered by the title and relating specifically or chiefly to the Upper Basin, its data and conclusions appear to conform reasonably well with official and generally accepted standards, supported by an ample direct knowledge of the subject, being therefore fairly immune to criticism. So much can scarcely be granted for the numerous references, detailed quantitative data, and generally questionable conclusions concerning the water supply of the Lower Basin. Here, material departures from reality are noted, as this has been slowly achieved in the midst of the Colorado desert by generations of difficult pioneering; after long-continued and involved litigation; through conferences and negotiations without beginning or end, and therefore timeless as all eternity (or so they seemed); with agreements and contracts for water, valued and guarded like the last drink in the desert canteen; and, above all, by about one-half billion dollars of new water-supply construction within the decade 1930–1940, practically all of which must be repaid at full interest rates and without grants, subsidies, or other financial jugglery.

The author concludes (heading "Irrigation Development") that "The [Colorado River] Compact is a comparatively simple document." A mere reading of it might well seem to justify this appraisal, but not to any one who has listened to leading legal luminaries argue the pros and cons of rival interpretations of its innocent-looking phrases through six humid, but far from humorous, weeks of a Washington, D. C., summer. This argument has been interrupted occasionally during the last decade, as a result of the generated or prevailing heat, but as yet (1940) is far from being concluded.

The statement under the heading "Distribution of Water Between Upper and Lower Basins" that Table 2 "is intended to show what restrictions the Colorado River Compact places upon the distribution of the water under these conditions" (run-off as of 1922 to 1937) and the heading of the same table "* * * Distribution of Water Between Upper and Lower Basins as Required by the Colorado River Compact," are insufficiently qualified. No such restrictions or requirements as those of Table 2 are really inherent in, or definitely derivable from, the Compact; these are rather an expression very largely of "personal equation," being involved in more or less arbitrary assumptions and estimates, and in individual or regional interpretations of the Compact terms.

---

[5] Hydrographic Engr., Met. Water Dist. of Southern California, Los Angeles, Calif.

The Compact appears, in simple language, to allocate 8 500 000 acre-ft to the Lower Basin and 7 500 000 acre-ft to the Upper Basin. Quite improperly, in Table 2, the author assigns, for ultimate consumption, 8 800 000 acre-ft to the Upper Basin (for a year with run-off such as 1929, for example) while allotting the Lower Basin 6 200 000 acre-ft (in addition to Arizona's Gila River water use, which that State's officials insist must be called no more than 1 000-000 acre-ft annually). The Compact is certainly more subtle than has been suspected, if this result is "required" by its terms or can even be derived plausibly from them. The point is raised merely because it involves a general Compact interpretation which can be simply and briefly explained and understood, differing thus from some of the more involved hydrological problems.

The author has provided (see heading "Distribution of Water Between Upper and Lower Basins"; explanation of Column (5), Table 2) for Upper Basin development "to the limit imposed by an average use of 7 500 000 acre-ft per yr"; but it is literally true that nowhere in the Compact does the word "average" appear. It can be agreed that this usual interpretation of the Compact allocation, as adopted by the author, may finally become accepted by custom, or may prevail after long litigation and adjudication as an "equitable" interpretation. However, it is not consistent with present appropriative water-right law and practice in the Upper Basin States, where an upper diverter is not permitted to increase his claimed or decreed water right in a wet year at the expense of lower water users, merely in order to average the effects of past or future dry seasons.

If such an average allocation had been intended by the Compact allocations, presumably it would have been explicitly stated, as in Article III (*d*) with reference to the progressive cumulative 10-yr aggregate run-off as guaranteed at Lee's Ferry. It is not implied that the Upper Basin cannot, under the Compact, make use of surplus water in wet seasons, particularly to refill empty reservoirs (which holdover storage is not charged as a use until in later years it is actually diverted and consumed), as long as the Lee's Ferry flow is not reduced below the guaranteed minimum and the Lower Basin is not prevented from receiving its full allocation. In the long run, however, such excess use as listed in Table 2 must permit less holdover storage in Boulder Canyon reservoir and therefore, in some degree, reduce the supply available for the Lower Basin. Of course, the Upper Basin has the right to assert a claim to such excess water after 1963, and then secure an allocation of it if such claim is valid and justified, but apparently it has no such right of assertion of such a definite claim at this time. However, the present specific criticism is simply that the author has adopted the Compact interpretation most favorable to his own locality, without making clear that other interpretations and quantitative results are possible and may be considered by some to be more reasonable and equitable, and to conform more strictly to the terms of the Compact.

As regards the data of Table 1, the author might be presumed to have obtained the Arizona portion from California representatives, and *vice versa* for the California "discrepancies." The new Gila Project, for example, is listed as including 2 900 000 acres but allotted only 405 000 acre-ft for ultimate annual consumption (minimum requirements there being 4.0 to 4.5 acre-ft per acre). This is clearly an individual judgment as to the probable rate of development of this desert area, but if its settlement should proceed more rapidly than thus assumed by the author, and Arizona should continue outside the bloc of Compact States, the set-up of Table 2 may prove surprisingly in error. The carefully "staked-out" future water supply now depended upon by the Upper Basin would presumably be subject to appropriation in Arizona for use on this Federal project, largely defeating the Compact's attempted long-range protection. However unlikely, this is merely another of the numerous contingencies or variations that prevent the author's computations from being, with any degree of definiteness and finality, the one set-up to meet Compact requirements. As long as Arizona is not a party to the Compact, and until the terms of this treaty are interpreted with somewhat more judicial disinterestedness than now seems the custom, a wide range of such set-ups, rather than one, appears necessary to present an adequate picture of future water supply possibilities in the Colorado River Basin.

The author views with some alarm the possibility of severe water shortages in the Colorado River Basin during future drought cycles, this fate seeming to be assigned chiefly to the Lower Basin, even as happens to lower rather than upper diverters on an irrigation ditch. Without entirely discounting this pessimism, it is believed to be subject to various qualifications. The present series of years of low run-off is a reminder of a similar but rather less severe drought period that terminated in 1905. There is some basis for the opinion that droughts as severe as the present one may have a frequency of not more than once in a century; but considering only the period of record, 1897 to 1939, the average is materially reduced below the probable long-time mean by the inclusion in the reckoning of two major droughts and only one intermediate wet cycle. The period 1905 to date (1940) probably gives a more accurate approximation to the long-time mean, and on this basis the early estimate of average virgin flow referred to in the paper (heading "Appraisal of Past Experience") as 17 000 000 acre-ft seems not more than 2% to 3% too high.

Such average flows are of real value only when regulated by holdover storage for use during droughts. The effective active storage of Lake Mead will be increased greatly, long before needed by the Lower Basin for water supply, by the construction of additional reservoirs in the Upper Basin. The Bridge Canyon Dam will promptly cut off practically all silt inflow to Lake Mead for many years into the future, and every up-stream reservoir will have the same effect in some degree. Upper Basin and canyon reservoirs will aid in flood-control regulation, permitting the ultimate reduction of the present Lake Mead flood-control reserve of 9 500 000 acre-ft to a nominal amount. Below Lake Mead, Parker and Bullshead reservoirs will conserve winter power water. Instead of the author's 20 000 000 acre-ft of available holdover storage, there will finally be functioning (by the time needed) between 30 000 000 and 40 000 000 acre-ft of active regulatory capacity. The outlook thus appears much less gloomy—in fact, very satisfactory.

Similarly, on the credit side of the ledger, Item 13, Table 1, for silt sluicing at Imperial Dam has shrunk to a negligible amount with the rapid clearing of the Colorado River water that has already occurred there. Doubt has also been expressed that sufficient discount has been allowed for the high elevations at which proposed large transmountain diversions must be made, reducing materially the portion of the available run-off that can be so diverted. Other such proposed transmountain projects involving high pump lifts must, even in drought years, allot sufficient water (and, incidentally, additional water above this minimum) to the canyon power plants to generate the power required for pumping if commercial power and resulting revenues to help pay for such projects are to be produced. Such natural and economic restrictions on excess Upper Basin diversions may well appear more reassuring to Lower Basin water users than even the guarantees of the Colorado River Compact.

The author's theory (heading "Distribution of Water Between Upper and Lower Basins"; explanation of Column (11), Table 2[6]) of large errors in Boulder Canyon reservoir areas and capacities, stated to be of the order of 5% to 10%, or several thousand acres, seems absolutely untenable, even in that difficult canyon region, in view of the high engineering standards of the Bureau of Reclamation, with Boulder Canyon reservoir itself the best possible proof that these standards have been maintained. A series of air-survey maps, flown at varied water-surface elevations, should be able to answer this question of stage-volume relationship quickly and with conclusive accuracy. Meanwhile, it is considered that the large, unaccounted inflow to Boulder Canyon reservoir cited under "Distribution of Water Between Upper and Lower Basins" (discussion of Column (10), Table 2) can be explained more satisfactorily as bank storage, since the allowance of 10-ft depth over increments of wetted area can be called "generous" only in comparison with earlier estimates of 3 ft for bank storage. At Jackson Lake reservoir, with a capacity of 847 000 acre-ft, but with a water-level rise of only 8% of that at Boulder Canyon reservoir, a bank storage inflow from 10% to 15% of the reservoir capacity has been measured. In any case, whether Lake Mead is larger than assumed, or has unexpectedly large bank storage, the water supply on the Lower Colorado River will be aided materially, in time of drought, by such an increase of active or effective storage.

The writer feels much sympathy for the paper's concluding plea (see heading "Conclusions") "for the use of available water supplies to expand [Upper Basin] communities already established" and "in ways and places that will, most effectively, build communities with a broad industrial base" in addition to agriculture. This need is called a "further justification * * * for the relatively high cost of these [proposed transmountain diversion] projects and the initial financial subsidization they need," and with the latter statement little disagreement will be found, even in the Lower Colorado Basin and among engineers (those least radical or politically minded of mortals). Search the paper as one will, however, no reference to, or explanation of, any primary or initial justification of such "subsidization" can be found to which this appealing "further justification" must presumably be intended to be added in order to give to such proposed projects at least semblance or approximation to economic feasibility. The promotion of such large-scale "subsidization" of water exports is the only factor ever seriously viewed by Lower Colorado River Basin water users as constituting a genuine threat to the permanent safety of their future water supply. To engineers in general, it remains an unpleasant and distasteful idea, foreign to their mental processes and professional standards.

---

[6] Also personal letter from author dated February 3, 1939.

Thomas C. Adams,[7] M. Am. Soc. C. E. (by letter).—Mr. Elder's discussion is directed mainly at two points. One is the accuracy and adequacy of the writer's analysis of the division of water supply between the Upper and Lower Basins and the apparent intended use of water in the Lower Basin. The other is the justification of Government subsidy for water-supply development.

Consider first the matters of water supply. Table 2 is an application of the water-supply partition provisions in the Colorado River Compact to the distribution of the water of the river (and purports to be nothing else). The writer was led to prepare it because one of the problems vital to Upper Basin interests is the quantity of water available to the Upper Basin under the compact provisions and in conformity with the actual flow of the river. Table 1, giving estimates of water likely to be demanded by Lower Basin projects, was prepared because some believe that aggressive advancement of irrigation and other water-supply construction in the Lower Basin, with consequent large demand for water, is likely to result in an encroachment upon water supply generally supposed to be reserved by the Colorado River Compact for the use of the Upper Basin. In so far as the Upper Basin is concerned, the Colorado River Compact had an outstanding purpose—namely, to reserve an equitable portion of the undeveloped supply in the river system so that the Upper Basin might find it available for use at any future time. Furthermore, it is now coming to be more firmly believed that if projects of the Lower Basin make use of quantities of water so large as to encroach on the water supply reserved by the Compact to the Upper Basin, this water cannot be recaptured for Upper Basin use even though the compact provisions are explicit. One factor supporting this view is that it would immediately appear uneconomical to restrict the use of water by an operating project which involves a large investment, works of monumental proportions, many human settlements spread over a vast area of land, and far reaching, established, economic relations, in order to permit this water to be used on other, undeveloped lands where works are to be built, and all economic and other social advances are to be made.

Within the ten years 1930–1940, large developments in both the Upper and Lower Basins of the Colorado River have been, and in the future most likely will be, involved with Government financing dependent upon Congressional approval (and as some view it, also involved with a measure, greater or less, of Government subsidy). Therefore, the possibility of developments involving the withdrawal of water from use in one locality for use in another, even in conformity with previous agreements and with acknowledged equities, appears even more unlikely. An important factor in such a situation is that the wrong that might be done is not to an individual but is a more or less intangible wrong done to a community or section of the country, a situation which does not elicit so strong a personal interest from those who might defend equities nor so strong a public opinion upholding action with the same intention.

---

[7] Associate Prof., Civ. Eng., Univ. of Utah, Salt Lake City, Utah.

All should take special note that the question of the desirability of a legal formula which would withhold a natural resource for development in a specific locality at a late date is not now under discussion. In so far as this applies to the water of the Colorado River System, it was decided by contract when the Colorado River Compact was drawn and ratified.

It will bear re-statement that Table 2 was prepared to show the application of the partition terms of the Colorado River Compact to a period of river flow actually occurring. The partition terms apply to the reconstructed flow that was presumed to take place under pristine conditions. The terms are comparatively simple, and the provision is one of the most important in the Compact. Complications arise mainly from vagaries of river flow and the minds of men. Both of these are very complicated indeed; but very few have been bold enough to state that the Compact provisions will be set aside.

In the preparation of Table 2 it was necessary, of course, to use some judgment in the selection and ordering of data. In the few instances, where choice was not precluded by the definiteness of the data and strictly mathematical nature of operations, the writer chose to give preference to data and interpretations from authoritative sources. Such is the case with values in Columns (4) and (5) which record the Upper Basin annual demands for water under conditions of actual development in corresponding years, and future intended development for conditions of these years under terms of the Colorado River Compact, respectively. It is to be noted that later in Column (12), Table 2, it is found that deductions from the latter values—those of Column (5)—for years after 1936 are necessary because of reduced water supply.

The values of Column (5), Table 2, are not a constant 7.5 million acre-ft per yr because, in years of high runoff, water users will be able, and will find it convenient, to divert somewhat more than they normally divert. Where diversion is made by many thousands of small ditches (a condition that exists in the Upper Basin), it would be a great feat of water administration—one that has not been generally accomplished—to correct this condition. In years of low runoff, conversely, diversions will be below average for similar reasons; but the departures of values in Column (5) from 7.5 million acre-ft are not great. The largest of the values, 8.8 for 1929—a year of rather great stream flow—should compare with 12.5 million acre-ft from direct river flow available to the Lower Basin during this same year, not with 6.2 million acre-ft as inferred by Mr. Elder. However, if a uniform 7.5 million acre-ft per yr had been assumed in Column (5), the important conclusions drawn from Table 2 would not have been changed—namely, that (1) the water supply is critically limited; (2) the water partition provisions of the Colorado River Compact, although satisfactory when the river flow is high or moderate, have peculiar, undesirable consequences on the distribution of water in the presence of intended (future, ultimate) Upper Basin use of water and when prolonged, but to be expected, droughts occur.

Conclusions originally made from Table 2 are emphasized when this table is extended using discharges actually recorded in 1938 and 1939 in place of the imaginary values at first used. These discharges have become available since the table was prepared. The actual discharge for 1939 was considerably less than the imaginary value first used. An addendum for Table 2 is given in Table 4 using the actual values of discharge for 1938 and 1939 and an imaginary value for 1940. Of most interest in this table is the indication that in 1940, to meet conditions previously explained, including the compact conditions in the presence of ultimate Upper Basin use of water, it would be necessary to permit to flow past Lee's Ferry all water draining from the Upper Basin during the year, plus an additional amount of 0.6 million acre-ft. This conclusion, based upon a rather large imaginary river flow assumed for 1940, seems fully valid because the prospect of a river flow in 1940 of as great as 15 million acre-ft at Lee's Ferry, the assumed value, seems quite unlikely at the present writing (May, 1940). River flow, coupled with men's attempts to read the future and provide for it, does seem very subtle.

TABLE 4.—Discharge of the Colorado River at Lee's Ferry, Presenting Distribution of Water Between Upper and Lower Basins as Required by the Colorado River Compact

(Addendum to Table 2; All Values in Millions of Acre-Feet per Year)

Year	Measured discharge, in millions of acre-feet per year	Ten-year cumulative discharges	Estimated Annual Depletion		Columns (2) and (4), minus Column (5)	Ten-year cumulative values from Column (6)	Measured discharge at Bright Angel, Ariz.	Ten-year cumulative values from Column (8)	Column (8) minus Column (2)	Annual estimated deficiencies	Water available for consumptive use	Annual discharge at Lee's Ferry based on conditions affecting Column (12)	Annual water supply, Lower Colorado River	Departures from cumulative sums of Column (14)	Cumulative depletion of Lake Mead
			Actual	Theoretical Future											
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)	(12)	(13)	(14)	(15)	(16)
1938	15.4	117.3	2.3	7.6	10.1	69.5	15.6	120.7	0.2	0.0	3.9	13.8	14.2	....	....
1939	9.4	107.5	1.8	6.2	5.0	61.4	9.6	110.9	0.2	−8.1	6.2	5.0	4.2	....	....
1940*	15.0	109.4	2.3	7.5	9.8	63.0	15.5	113.0	0.5	1.6	−0.6	17.9	18.4	....	....

* Values for 1940 are imaginary—believed based upon a discharge at Lee's Ferry, not likely to be reached.

The writer does not believe one can depart materially from the data of Tables 2 and 4 or the conclusions drawn therefrom while conforming to the terms of the Colorado River Compact and to the generally accepted interpretations.

Of course one must admit the possibility of other dispositions of Colorado River water. Large quantities of water may be absorbed in Mexico by appropriation sustained by international courts or by treaty grants. Arizona, not subscribing to the Compact, may legally appropriate a large quantity of water prior to its appropriation elsewhere and find ways of financing construction of necessary works. However, the vast expenditures required for water-supply development in Arizona must apparently be financed by the Federal Government and approved by Congress. Therefore it would appear that large-scale developments made contrary to the stipulations of the Colorado River Compact would involve flagrant violation of trust by the United States Government which is a party to the Compact. On the other hand, the Upper Basin may not desire to construct, or may be unable to finance, works in the Upper Basin and therefore water could be used elsewhere without protest. These and perhaps other possibilities exist, but they are not in accord with the preponderance of the opinions with which the writer is familiar.

The peculiarities of water distribution imposed by the Compact during drought periods appear to require an eventual modification of Compact provisions.

Referring to Table 1, which indicates the prospective water supply to be drawn reasonably soon from the main Colorado River below Lee's Ferry, the writer of necessity relied upon his own judgment to sort out acceptable items from the considerable quantity of discordant data. It again may be emphasized that an effort was made to be guided more by what is on the ground or posted on financial books and relatively less by statements of intentions.

Further comment may be made with respect to the Gila Project which was considered in Items 5 and 6 of Table 1. The construction of irrigation works for the first unit of this project, approximating 150,000 acres, is well advanced (May, 1940). So far as is known, there are not definite plans with respect to the time of construction and financing of additional works for other units of this project. The use of the term "Gila Project" by the Bureau of Reclamation is limited to an area of about 500,000 acres mentioned in the explanation accompanying Table 1. The value 2,900,000 acres was placed in Table 1 to indicate the extent of what some consider the possibilities of irrigation development in the Gila Valley. (Proposals, large and differing in detail, for the irrigation of areas approaching 2,900,000 acres in the Gila Valley of Arizona, are occasionally referred to as the Gila Project.) The writer did not go beyond an annual allotment of 405,000 acre-ft from the Colorado River to the Gila Project because this is ample water to supply the unit of the project for which there is assurance that works for its irrigation will be built; and also because each further appropriation of water for continuing use in the Lower Basin appears to add to a total which is already close to contravening the partition provisions of the Colorado River Compact. One would likely hold that, under the Compact, the irrigation of 2,900,000 acres of land in the Gila Valley of Arizona would require all water reserved for Lower Basin use.

A discussion of the fundamentals usually offered in justification of subsidies to irrigation and other water development in the United States was not the object of the paper. In the end, Government subsidization of water development or any other development is based on expediency, established policy, availability of money or credit, the adequacy of favorable sentiment, and other items. The final decision is made in political circles.

Unified judgment of the justifiableness of subsidization would be almost impossible to obtain. Even agreement of what constitutes subsidization seems impossible. Some will regard repayment of a Government investment in an irrigation project by 40 annual payments of 1/40 the first cost and without interest as complete repayment. (This is the present repayment plan of the Bureau of Reclamation—it governs repayment of advances for the construction of the All-American Canal which was built to convey Colorado River water to the Imperial Valley.) Others will compare this to a commercial investment which requires repayment in the same length of time, with interest at, say, 5%, and find the annual commercial repayment is 2.3 times the other. The latter, therefore, may conclude that the 40-yr repayment without interest is equivalent to approximately a 57% subsidy. If a Government rate of interest of 3% is taken, the subsidy which may be concluded is 42 per cent. The first WPA plan of financing (a portion of Parker Dam was financed in this manner) involved what is usually referred to as a 30% subsidy or "grant."

Referring generally to Government water-supply financing in the United States—after a general financing policy has been determined and applied, it has been true too often that subsequently "adjustments," "moratoria," and "commutation of payment" have intervened so that cost repayments have been considerably less than were originally anticipated. Members of the engineering profession of recognized high standing occasionally have supported these modifications as being entirely justified and sufficiently common so that they are regarded as a likely if not an inevitable consequence of Government financing and therefore that Government financing is tantamount to subsidization. Nearly all of the new water-supply construction involving approximately a half-billion dollars and forming part of the development of the Colorado River below Lee's Ferry has been financed by the Government, and concessions (for instance, reduction of the interest rate of the Reconstruction Finance Corporation to the Metropolitan Water District of Southern California from 5 to 4⅛%) have already been granted. In April, 1940, a determined effort was being made before Congress to obtain legislation permitting a reduction in the interest rate applying to repayments of the Government's investment in the Hoover Dam from 4 to 3 per cent. The bill embodying this change seems to have the benediction of all concerned. It also provides for deferring the beginning of repayment of that portion of the cost of the Hoover Dam which was allotted to flood control for about 50 years. Some will regard this as a substantial measure of subsidy and back their arguments with financial computations.

Throughout the American West, there is general agreement that Government subsidization of irrigation development to the extent of the current Bureau of Reclamation (Department of Interior) plan of financing is justified. Few advocate subsidization beyond this. It is the policy now in operation. Literature stating the pros and cons is voluminous. There is no need for the writer to re-state the case or particularly support it.

In Mr. Elder's discussion, mention is made of some technical points of hydrography. One is the apparent excessive loss from Lake Mead (not necessarily all real loss). Present data and their analyses seem to support fully the existence of excessive apparent loss and to indicate that a portion of the loss is genuine. It is probable that aeroplane surveys, which were referred to, and more data from the operation of the reservoir, will help to decide the nature of losses.

A second hydrographic point is the probable frequency of major drought periods. In this connection it is generally becoming apparent, even to optimists, that the region is having one drought that is truly severe. Data regarding recurrence of major droughts are indirect or only inferential. The First

Annual Report of the Metropolitan Water District of Southern California states:[8]

> "By analyses of old flood records, mission crop reports, miscellaneous notes, diaries of early settlers, and other indirect means, H. B. Lynch, consulting hydraulic engineer of Los Angeles, has extended these [meteorological] records with reasonable dependability back to the year 1769. The results show that there has been no change in mean climatic conditions in Southern California since that date at least, although drought periods are indicated that were both more severe (1822–32) and of longer duration (1842–83) than any that have occurred during the present century."

A third hydrographic point is the amelioration possibility of additional large reservoirs. This is a possibility, but the beneficial effects of reservoirs are strained by the evaporation at the water surface and the long hold-over storage required in connection with the Colorado River. The writer would emphasize in this connection, and in some others regarding the hydrography of the Colorado River (or other rivers), that statements of general effects of hydrographic components on the solution of hydrographic problems may be misleading. In place of dependence on such statements it is recommended that an analysis be made by suitable periods, and for each, to apply the conditions with respect to withdrawals and losses of water as they would occur and credit accretions of water provided by natural conditions and the conditions provided by judicious management of available water resources. All must be conducted with due regard to the fact that at any assumed time no extensive knowledge of future conditions is available other than general knowledge indicated by past experience. Pronouncements of how river discharge is to be regulated or distributed (based upon knowledge of average flows and unsupported statements of how reservoirs affect stream regimen) should be subjected to careful scrutiny.

A fourth hydrographic point is the prospective quantity of water that will be lost at or below Imperial Dam. In the preparation of Table 1 a rather low value for this loss was selected from among several authoritative statements of much larger values. Included in the losses in question, in addition to that required for silt sluicing, are: Incidental flood spill, return drainage water allowed to flow to waste because of high salt content, inevitable wastage from irrigation canals, and possible wastage of part of the power water on the Yuma Project or on the All-American Canal near the heading of the Imperial Canal.

AN IMPROVED METHOD FOR ADJUSTING LEVEL AND TRAVERSE SURVEYS

BY CLARENCE NORRIS,[1] ESQ., AND JULIUS L. SPEERT,[2] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. GEORGE H. DELL, HOWARD S. RAPPLEYE, R. M. WILSON, CLEVELAND B. COE, GEORGE D. WHITMORE AND C. C. MINER AND W. O. BYRD, ROBERT C. SHELDON, AND CLARENCE NORRIS AND JULIUS L. SPEERT.

SYNOPSIS

A simplified method for adjusting level and traverse surveys is presented in this paper. The results are identical with those obtained by least squares, but the method is so simple as to be understandable by any one possessing an elementary knowledge of algebra and surveying. The labor required for this method of adjustment is considerably less than that required by the usual least-squares methods, and is no greater than that of cruder methods.

The paper is divided into three parts: The main body gives detailed instructions for the adjustment, in such form that the computations may be performed by a clerk familiar with the use of a computing machine. For the benefit of those interested, the theory of this method is developed in Appendix I; and Appendix II explains a simple method of solving the adjustment equations.

INTRODUCTION

All surveys, whether for the determination of altitudes or of relative horizontal positions, are subject to two general types of error—systematic and accidental. Before any adjustment of a survey is attempted, all known systematic errors should be removed, leaving only those of the accidental type to be disposed of by the adjustment.

Frequent azimuth checks are usually made in a well-conducted traverse survey. A preliminary angle adjustment can be applied, therefore, before the computation of latitudes and departures is undertaken. The angle adjustment is so simple and well understood that it will not be discussed herein.

NOTE.—Published in October, 1939, *Proceedings*.

[1] Asst. Topographic Engr., U. S. Geological Survey, Washington, D. C.

[2] Asst. Topographic Engr., U. S. Geological Survey, Washington, D. C.

When latitudes and departures—or differences of latitude and longitude—have been computed for each course in a traverse net, some error will usually appear in the form of imperfect closures in the net. This error is due to two general causes—accidental errors in the straight-line measurements (including other errors treated as accidental), and errors of direction that still remain after the preliminary adjustment of the angles. Because of the complex interrelationship of these errors, and the practical difficulties involved in their separation, it is customary, except in the most precise surveys, to treat the traverse closure as a single accidental error with two components; namely, northing and easting (or latitude and longitude). In this paper it is assumed that all preliminary computations have been performed and that unadjusted north and east coordinates have been determined for both extremities of each line in the net. The resultant closure errors, in northing and in easting, will be treated as independent items, either of which may be adjusted without regard for the other.

Similarly, in a level net, the error will appear as imperfect closures, or differences of elevation, at the junction points. The method of adjustment to be described is applicable equally to a level or traverse net; but, because the latter presents a more general problem, having two errors to be adjusted, special attention will be given to the adjustment of a traverse net.

ADJUSTMENT OF A TRAVERSE NET

The method of adjustment to be described herein is based on the so-called "Junction Point method" for the adjustment of levels developed by Mr. D. H. Baldwin of the U. S. Geological Survey.[3] The theory of the new method is presented in Appendix I of this paper.

To illustrate the method and its application to traverse adjustment, a somewhat involved traverse net will be adjusted in detail. This net is shown diagrammatically in Fig. 1, with the junctions numbered for identification. The stations whose positions are to be held fixed as a result of earlier adjustment or of a more precise survey are indicated in Fig. 1 and are listed in Table 1 with their fixed positions. The results of the preliminary computations of north and east coordinates are listed in Table 2, the upper entry representing

the beginning, and the lower entry the end, of the line indicated in Column (1), in accordance with the direction arrow on the line in Fig. 1. The items in Columns (4) and (5), Table 2, are for the computer's reference to the original computation books. Column (7) identifies the stations at the extremities of the various lines, as shown in Fig. 1. The positions shown in Tables 1 and 2 have been computed in plane coordinates. However, this method may be used equally well for adjusting a traverse in geodetic coordinates, differences of latitude and longitude being substituted for differences of northing and easting in the adjustment computations.

Special Conditions.—A few special and unusual conditions are included herein to show how such conditions may be treated in an adjustment. It will be noted that line *h* in Fig. 1 crosses line *q* without tying to it. The omission of a junction at this point merely eliminates one equation from the adjustment and presents no special problem. Although lines *f* and *n* were surveyed independently in the field, they are in reality a single line in spite of the closure between them, and they are treated as one line in the adjustment, the weight being that of the two lines combined. The same treatment could be applied to lines *i* and *k*; but, to illustrate the method, these are treated as separate lines, closing at junction 8 as indicated.

Junction Closures.—A junction closure is the distance by which the computed position of a point on one line differs from the computed position of the same point on another line. It is positive if the computed position on the closing line is the greater, and negative if it is the smaller. Stated otherwise, the junction closure is the distance that must be subtracted algebraically from the position on the closing line to obtain the corresponding position on the line or station closed upon. A junction closure is indicated by a short arrow parallel to the closing line, pointing toward the line closed upon, and by numbers representing the magnitude of the break or closure. The junction closures indicated in Fig. 1 are derived from inspection of Tables 1 and 2. For example, junction 1 is at the end of line *c* and the beginnings of lines *d* and *e* at station *T* 3. The position of station *T* 3 is the same on all three lines (see Table 2); therefore, zero closures are indicated between line *e* and lines *c* and *d*. The absence of a closure arrow at the extremity of any line implies a zero closure for that line on the junction involved. At junction 4, station *T* 5 has the same position on lines *g*, *h*, and *j*; but cn line *s* its position is 5.37 less in northing and 2.59 less in easting. Therefore, line *s* closes on junction 4 with closures of − 5.37 and − 2.59, as indicated. The position of station *C* on lines *e* and *f* is 4.02 greater in northing and 0.03 less in easting than the fixed position of station *C* (Tables 1 and 2), as indicated by the closures of these lines on the fixed station. Line *r*, Fig. 1, starts at station *C* with the correct final position, and its closure on *C*, accordingly, is zero. All closures, at junctions and at fixed stations, are determined in the same manner. When dealing with items of northing and easting, it is desirable always to write the northing quantity first, thereby avoiding confusion as well as the necessity of labeling each item.

Circuit Closures.—As the next preliminary step in the adjustment, it is desirable to investigate the circuit closures. Although these do not enter directly into the adjustment, they offer a key to the quality of the field work and preliminary computations, indicating places of apparent weakness and frequently aiding in the discovery of blunders.

The circuit closures may be computed by adding all junction closures counterclockwise around each circuit, changing the sign of a junction closure if its closure arrow is opposed to the counterclockwise route around the circuit. For this purpose, a group of lines connecting two fixed stations is treated the same as a closed circuit. In Fig. 1, the circuit closures are shown within the respective circuits, inside a curved arrow which indicates the direction of closure. Each circuit closure, and all the junction closures contained in it, may be checked from Tables 1 and 2 using Fig. 1 as a guide. Proceeding counterclockwise around the circuit as before, subtract the position of the beginning, and add the position of the end, of each line whose direction arrow agrees with the direction of progress around the circuit; reverse the operations, adding the beginning and subtracting the end, for each line whose direction arrow is against the direction of progress around the circuit. If a circuit connects two fixed stations, assume an imaginary line joining them, and treat the fixed positions as the extremities of this imaginary line. The circuit closures obtained by this method should check exactly those determined previously. Any discrepancy might be due to a mistake in the determination of the circuit closure by either method, or to a mistake in one or more junction closures, or to a combination of these mistakes.

The magnitude of any circuit closure in relation to the length of its circuit is a measure of the precision of the survey around that circuit. An excessively large closure might clearly indicate the existence of a gross blunder and lead to its detection. Large closures of opposite signs in two adjoining circuits indicate weakness, or possibly a blunder, in the line common to these circuits. In general, the algebraic difference between the circuit closures on opposite sides of any line may be used to form a rough preliminary estimate of the correction that the adjustment may be expected to force into that line. Thus, any line that appears to be below the standard of the remainder of the work may reasonably be omitted from the adjustment, in order that its weakness shall not detract from the strength of the remainder of the survey.

Weights.—In the adjustment of a level net, the lines are weighted inversely as their relative lengths. For a traverse, however, it is believed that the number of transit stations in a line offers a better index of the strength of that line. For convenience in solving the adjustment equations, to avoid coefficients either too large or too small, it is desirable that the magnitude of the diagonal terms of the equations be between 1 and 10. This condition can be produced most readily by using weights for the lines, such that their average value will be about 1. Therefore, the effective length of, or number of stations in, each line should be divided by the approximate average of all the lengths, or numbers of stations, before weighting. In this adjustment the lines will be weighted in inverse ratio to the number of stations in each, and the weight of each line in this example will be taken as 50 times the reciprocal of the number of stations in it. The number of stations in each line is listed in Table 2, and the weights are marked on the lines in Fig. 1.

As the preliminary positions and the closures have been computed to two decimal places, it is desirable that the weights be used to one place more, or three places, in order that there shall be no loss of accuracy due to uncertainty in the last decimal figure. If any line has been surveyed with greater or less care than the others, to entitle it to special consideration, its weight factor may be changed accordingly. In this example all lines are considered of equal strength.

Adjustment Form.—After the preliminary examination and preparation are completed, the adjustment may be begun. All junctions between lines of the survey should be numbered, except where lines meet at a fixed station. Thus, there should be a number for each junction for which a correction is to be determined. The form for the table of equations (Table 3) should be prepared, allowing one column for each numbered junction, two absolute columns, and an additional column on each side of the table for later use. Four lines should be allowed for each equation except the first, which requires only three. These groups of lines should be numbered in the same order as the column headings, and the first three lines in each group should be designated *a*, *b*, and *c*, respectively. The fourth line is left blank as a separation between the equations.

In the first equation lines *a* and *b* are combined. As a further guide, a horizontal line may be ruled above each *b*-line.

Equations.—The adjustment equations may now be formed by inspection

TABLE 4.—SOLUTION OF ADJUSTMENT EQUATIONS

Equation	R	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	N	E	S
(1) *ab*	0.284657	−3.513	+1.042							+ 5.593	+9.134	+12.256

from Fig. 1. For this purpose, as well as for the solution, a computing machine is almost indispensable. The original equations are written on the *a*-lines, the other lines being reserved for their solution. The diagonal term for each equation is entered in the line and column bearing the number of the corresponding junction, and is always negative. The coefficient of each of the remaining terms of an equation is entered to the right of the diagonal terms, on the line and in the column corresponding to the extremities of the corresponding line in the survey, as will be illustrated.

Diagonal Terms.—The diagonal term for any equation is the negative sum of the weights of all lines entering the correspondingly numbered junction. For example, at junction 1, Fig. 1, it is − (1.042 + 1.562 + 0.909) = − 3.513, as entered in Column (1), line 1*a*, Table 3. For junction 2, it is − (0.862

+ 1.042 + 0.833) = − 2.737, as entered in Column (2), line 2*a*. Similarly, all diagonal terms are determined from Fig. 1, and entered in Table 3, in the *a*-line and column corresponding to the number of the junction involved.

Coefficients.—The remaining coefficients in Equation (1), Table 3, are the weights of the individual lines entering junction 1 from the other numbered junctions. For example, line *c* enters junction 1 from junction 2, and + 1.042 is entered in Column (2), line 1*a*; lines *d* and *e* enter junction 1 from fixed stations and have no coefficients in the table. Similarly, line *b* enters junction 2 from junction 3, and + 0.862 is entered in Column (3), line 2*a*; line *t* enters junction 2 from junction 5, and + 0.833 is entered in Column (5), line 2*a*; line *c* enters junction 2 from junction 1, and + 1.042 is found to be already entered in Column (2), line 1*a*. It is not entered in Column (1), line 2*a*, because that space is to the left of the diagonal term, and only those spaces to the right of the diagonal terms are used. In like manner, the coefficients for all the equations are entered in Table 3.

Absolute Terms.—The absolute terms for northing and easting of each equation may now be computed and entered in Columns N and E, respectively. Each of these terms is the sum of the weighted closures of all lines entering its junction; it is the sum of the products of the weight of each line entering the junction by the sum of the closures in that line computed from the contiguous junction. It is essential that the sign and direction of each closure be observed carefully, the closure sign being held if its direction is toward the junction whose equation is being determined, and reversed if its direction is from the junction. For example, N for Equation (1) is 1.042 (0) + 1.562 (+ 5.92) + 0.909 (− 4.02) = + 5.593; E is 1.042 (0) + 1.562 (+ 5.83) + 0.909 (+ 0.03) = + 9.134. Similarly, for Equation (7), N = 0.625 (+ 7.67 + 4.85) + 0.397 (− 4.02 + 1.46) + 0.746 (0) = + 6.809; E = 0.625 (− 3.86 − 3.68) + 0.397 (+ 0.03 − 7.69) + 0.746 (0) = − 7.754. The absolute terms should be computed to the same number of decimal places as the coefficients.

When all the absolute terms have been computed and entered in Table 3, the adjustment equations are complete and may be checked. The absolute terms should be checked first, as follows: Compute the weighted closures of all lines into all the fixed stations in the same manner in which the absolute terms were computed; write the sum of all these northing closures (+ 3.741) at the bottom of the (N)-column and the sum of all these easting closures (− 2.992) at the bottom of the (E)-column. Including these items, the sum of all entries in each of these columns should be zero, or very nearly so. A small discrepancy in the last place may be due to the rounding off of residual decimals beyond the last significant figure. If preferred, the (N)- and (E)-columns may be checked simultaneously by recording only the sum of the northing and easting closures into the fixed stations (+ 0.749), and adding this to both columns to equal zero.

In computing all sums of products, the individual products need not be recorded, but should be accumulated in the computing machine. For this purpose the decimal points should be placed properly on all the dials, and should be observed carefully in all operations. Only the keyboard and multiplier dial are cleared after each multiplication, the product being left in the machine. Negative products are obtained with the reverse multiplier. The product dial is cleared only when the desired sum has been recorded.

(S)-Column.—The (S)-column at the right of Table 3 offers a further check on the formation of the equations, as well as a step-by-step check on the solution. The (S)-item for each equation is determined by adding to the negative sum of the weights of all lines entering a junction from fixed stations the entries in the (N)-column and (E)-column. For example, at junction 1, lines *d* and *e* enter from fixed stations; therefore S1 equals minus the sum of the weights of these lines plus N plus E, or $-(1.562 + 0.909) + 5.593 + 9.134 = +12.256$. At junction 3, only line *a* enters from a fixed station; hence $S3 = -2.174 + 0.000 + 0.000 = -2.174$. There are no fixed stations contiguous to junction 2; therefore, S2 equals the sum of N and E, or $-4.865 + 0.367 = -4.498$.

When the (S)-column is completed, the sum of all entries on line 1*a* through N and E should equal S1 exactly. The sum of all entries in Column (2) and on line 2*a* through N and E should equal S2. Similarly, the sum of Column (3) and line 3*a* should equal S3. Thus, each equation is checked by adding its column down to the diagonal term, then across through E, to equal its (S)-entry. A mistake in any coefficient will appear as a discrepancy in the check of the two equations containing that term. A discrepancy peculiar to a particular equation indicates a mistake in either its diagonal term or its (S)-term.

Solution of Equations.—The equations in Table 3 may now be solved by the Doolittle method[4] as shown in Table 4. The detailed solution especially adapted and simplified for use with a computing machine is explained with complete instructions in Appendix II. The (N)-, (E)-, and (S)-columns are treated identically in the forward solution, the check on the (S)-column being applied in the usual manner after each step. In the back solution, an independent computation is made for CN, CE, and CS for each equation, using only the appropriate items for each, and omitting the other two quantities from each computation. The back solution is checked, step by step, by adding CN, CE, and -1.0000 for each equation; the sum should equal CS for that equation, very nearly.

Corrections.—The (CN)- and (CE)-items of the back solution are the required corrections to be applied to the corresponding junctions of Fig. 1. These are rounded off to two decimal places and are shown in small rectangles with arrows pointing to the line at the extremity of which the correction is applied. It should be borne in mind that these corrections apply to the position closed upon at each junction. The correction to the extremity of the closing line may be determined by subtracting the junction closure from the computed correction. Thus, at junction 1, the computed correction applies equally to lines *c*, *d*, and *e*. At junction 7, the computed correction applies to lines *m* and *n*; the northing correction to the end of line *q* is + 0.97 − (+ 4.85) = − 3.88; its easting correction is − 4.13 − (− 3.68) = − 0.45. The corrections to lines at fixed stations are equal and opposite to the closures on these stations. The difference between the corrections at the ends of a line represents the correction to be distributed or prorated through the line.

---

[4] "Adjustment of Observations," by T. W. Wright and J. F. Hayford, Second Edition, pp. 114–121. Detailed instructions for the solution are given in several publications of the U. S. Coast and Geodetic Survey.

Final Test.—At this point the adjustment of the junctions is complete, corrections having been determined for each extremity of each line. One final check may be applied, however, to test the efficacy of the adjustment. According to the theory of least squares, the most probable values for the corrections should satisfy the condition that the sum of the weighted corrections applied to all lines around a given junction will be zero. This test may be applied around each numbered junction by multiplying the weight of each line entering it by the difference of the corrections applied to its extremities. For this purpose, the N- and E-corrections may be tested together, the corrections at the far end of each line being applied with their proper signs, and those at the near end with reversed signs. For example, at junction 1, 1.042 (− 0.98 + 1.80 − 1.30 − 3.13) + 1.562 (+ 5.92 + 5.83 − 1.30 − 3.13) + 0.909 (− 4.02 + 0.03 − 1.30 − 3.13) = + 0.02. In view of the number and magnitude of the items included in this test, the discrepancy of 0.02 is reasonable, and indicates a satisfactory adjustment. The same test may be applied to all numbered junctions in the net. In using lines *f* and *n* to check at junction 7, the break at station *T* 4 should be considered, thus: 0.397 (− 4.02 + 0.03 + 1.46 − 7.69 − 0.97 + 4.13) + 0.746 (0.00 + 0.00 − 0.97 + 4.13) + 0.625 (− 0.48 − 3.15 + 3.88 + 0.45) = − 0.01. In this example, the discrepancies at the eight numbered junctions vary from 0 to 0.02, with an average value of 0.009.

SUMMARY

A brief summary of the operations required for a complete adjustment may be of value in the formation of a mental picture of the entire process. For a traverse net, the preliminary computations should be completed and the N- and E-coordinates, or the latitude and longitude, should be determined for each junction. For a level net the orthometric elevation of each junction point should be determined. Then the operations of the adjustment should be performed in the following order:

1.—Prepare a diagram of the survey, showing junction closures, circuit closures, and weights of all lines. Number all junctions, except those at fixed stations.

2.—Prepare a form similar to Table 3 for the adjustment equations.

3.—Compute the diagonal terms as the negative sum of the weights of all lines entering each numbered junction.

4.—Enter the weight of each line in the space numbered according to the junction numbers at the ends of that line, using only those spaces to the right of the diagonal terms.

5.—Compute and enter in the (N)- and (E)-columns, respectively, the weighted closures in northing and easting of all lines entering each numbered

junction. In a level adjustment, of course, there would be only one absolute column.

6.—Check the (N)- and (E)-columns by summing them to zero with the weighted closures of all lines entering all fixed stations.

7.—Compute the (S)-entry for each equation as the negative sum of the weights of all lines entering its junction from fixed stations, plus its (N)- and (E)-entries. Add each equation down its column to its diagonal term, then across through its absolute terms to equal its (S)-term, exactly.

8.—Solve the equations by the Doolittle method, forward and back solutions.

9.—On the adjustment diagram, enter the results of the back solution as corrections to the lines closed upon at the numbered junctions.

10.—Subtract the junction closures from the computed corrections to determine the corrections at the ends of the closing lines.

11.—Test the adjustment by comparing with zero the sum of the weighted corrections in all the lines around each numbered junction.

12.—Distribute or prorate the difference between the end corrections of each line to the stations in that line, to complete the adjustment.

CONCLUSION

It is believed that the results of any survey, even a poor one, can be improved by appropriate adjustment, so that all parts of the survey shall fit together with mathematical nicety after the computations are completed. In other words, any survey worth making is worth improving at small additional cost by careful adjustment. The relatively small cost of adequately adjusting a survey undoubtedly improves the results to a greater degree than could be obtained by a similar expenditure for improved field technique. Obviously, poor work cannot be made good by adjustment, but the data resulting from any survey can be improved in value and usefulness if all mathematical inconsistencies are removed. When the funds available for a survey are limited, it is believed desirable to reserve a portion of the money for the purpose of adjustment.

In traverses, except for the most precise geodetic surveys, it is customary to combine all accidental errors in the closures of latitude and longitude, or latitudes and departures. In this respect, practically all methods of adjustment agree. Beyond this, variations exist, from adjustment by "estimation" or judgment to adjustment by least squares. For any adjustment, regardless of method, it is desirable that a diagram be prepared to show the various closures and the relative weights of the respective lines. The diagram, although not an essential part of the adjustment, is an invaluable aid in the determination and distribution of the adjustment corrections.

It is generally recognized that the method of least squares offers the best adjustment possible in accord with the theory of probability. Although the method described herein is not derived through a consideration of the squares of residuals or errors, it is based on the principle that the correction at any

junction shall be a weighted mean of the corrections brought in from the contiguous junctions (see Appendix I). This principle is in perfect harmony with the principle of least squares, and the two methods give identical results.

It may be emphasized, furthermore, that the adjustment equations that are set up by inspection from the adjustment diagram are identical in every respect with the normal equations that would be obtained by the use of the observation-equations method in least squares. This new method has a definite advantage over the latter in that the equations may be written by inspection, requiring no auxiliary tables. It has similar advantages over the condition-equations method, in that a table of correlate equations is not needed, and the solution of the adjustment equations gives the desired corrections directly, without the necessity of applying the correlates to the correlate equations and computing the line corrections before the junction corrections can be determined.

It is believed that the method of adjustment described herein is so simple as to be easily understood by any one familiar with the elements of surveying and of algebra. Although the Doolittle method is suggested as the shortest known method of solving the type of simultaneous equations obtained, these equations may be solved equally well by the usual algebraic methods. (For algebraic solution, the equations should be written in complete form; see Appendix I.) Although the method described is identical with least squares, it is not expected to have the psychological effect that the name "least squares" has upon most surveyors—the suggestion of something too complicated to be understood except by an expert mathematician. Some technical understanding is helpful, of course, in preparing and studying the closure diagram, but the mechanics of the adjustment are such that, if the instructions are observed carefully, a complete adjustment can be made by a clerk familiar with the use of the computing machine.

As compared with cruder methods of adjustment, this method requires little additional work for the theoretically most probable distribution of the errors. The only work peculiar to this method is the writing and solving of the simultaneous equations. In this respect there is a compensating saving of labor, particularly in a traverse adjustment, in that corrections for both north and east coordinates are obtained simultaneously, whereas in most methods these must be adjusted separately. As compared with the Baldwin method for a level adjustment, this method gives a more balanced adjustment, eliminates the need for exercise of judgment in the selection of junctions, and permits adjustment of an entire network at a single set-up. The time required for adjusting an ordinary level net by this method compares favorably with that required by the Baldwin method.

Because this method is suitable for the adjustment of any type of line survey, another possibility becomes apparent. In many surveys it happens that traverse and levels are run over the same routes for the purpose of determining horizontal and vertical control for all monuments. If the lines are so run that the weights to be used for adjusting the levels are in the same ratio as the weights to be used for adjusting the traverse, or can be made so, then both traverse and levels can be adjusted at the same time by using three absolute columns in the adjustment equations instead of one or two. With three absolute columns, the (S)-column should include the effect of all three, and the solution may be completed in exactly the same manner.

ACKNOWLEDGMENTS

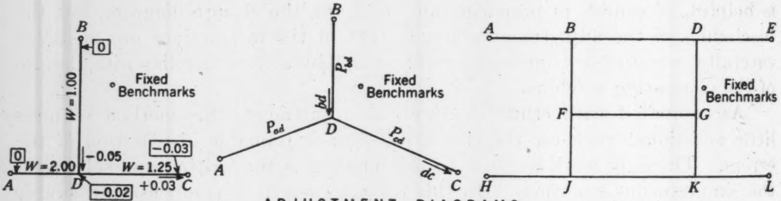
This method of adjustment was developed in the Section of Computing, of the U. S. Geological Survey, between 1936 and 1938. The short-cut approach to the theory through simple algebra was suggested by Mr. Norris; Mr. Speert arranged the mechanics of the adjustment in collaboration with other members of the Section. This paper is published by permission of the Director of the Geological Survey, United States Department of the Interior.

APPENDIX I

THEORY

As a necessary preliminary to the development of the new theory, the Baldwin method will be reviewed briefly.[3]

In the simple level net shown in Fig. 2, line *A D C* runs from bench mark *A* (the elevation of which is fixed) to another fixed bench mark, *C*, closing on bench mark *C* with an error of + 0.03 ft as indicated by the small arrow at point *C* and the number + 0.03 (this means that the elevation of bench mark *C*, as determined by line *A D C*, is 0.03 ft greater than the fixed elevation of bench mark *C*). Similarly, line *B D* begins at fixed bench mark *B* and closes on bench mark *D* with an error of − 0.05 ft (or the elevation of bench mark *D* as determined by line *B D* is 0.05 ft less than the unadjusted elevation determined by line *A D C*). Assume also that the lengths of *A D*, *B D*, and *D C* are 5, 10, and 8 miles, respectively.



ADJUSTMENT DIAGRAMS

FIG. 2 FIG. 3 FIG. 4

For the adjustment, the lines are to be weighted inversely as their lengths or in the ratio 2.00 : 1.00 : 1.25, as indicated in Fig. 2. This adjustment is based on the principle that the adjusted elevation of bench mark *D* is to be a weighted mean of the elevations brought in through the various lines tying to it. This principle is in strict accord with the principle of least squares and may be readily derived from it. The weighted mean is most conveniently obtained by considering corrections and closures instead of actual elevations. The correction to line $A\ D$ at point A (as shown in a small rectangle in Fig. 2) is zero; the correction to line $C\ D$ at point C (to correct the closure of + 0.03 ft) must be − 0.03; the correction to line $B\ D$ at point B is zero. As there are no breaks in continuity between bench mark D and the indicated corrections at points A and C, the corrections at these points may be used for weighting at point D; in order to refer to a common elevation at point D, the closure of − 0.05 must be added to the correction at point B before the latter may be weighted at bench mark D. Then the weighted correction at point D may be computed as the sum of the products of the various line corrections by the weights of their respective lines, divided by the sum of the weights; that is,

$$D = \frac{2.00(0) + 1.00(-0.05) + 1.25(-0.03)}{2.00 + 1.00 + 1.25} = -0.02 \text{ ft.}$$

To express this principle in a general equation (see Fig. 3), let A, B, C, and D represent the corrections at points A, B, C, and D, respectively; ad, bd, and cd represent the mathematical breaks or closures in the lines A to D, B to D, and C to D, respectively; and P_{ad}, P_{bd}, and P_{cd} represent the weights of the respective lines. Then $D = \dfrac{P_{ad}\,(A + ad) + P_{bd}\,(B + bd) + P_{cd}\,(C + cd)}{P_{ad} + P_{bd} + P_{cd}}$;

or

$$(P_{ad} + P_{bd} + P_{cd})\,D = P_{ad}\,(A) + P_{bd}\,(B) + P_{cd}\,(C) + P_{ad}\,(ad) + P_{bd}\,(bd) + P_{cd}\,(cd) \qquad (9)$$

Transposing all terms to the right side of the equation,

$$0 = -\,(P_{ad} + P_{bd} + P_{cd})\,D + P_{ad}\,(A) + P_{bd}\,(B) + P_{cd}\,(C) + P_{ad}\,(ad) + P_{bd}\,(bd) + P_{cd}\,(cd) \qquad (10)$$

Note that cd represents the closure or breaks in the line C to D, whereas dc represents the same closure or breaks in the reverse direction; thus,

$$cd = -\,dc \qquad (11)$$

Equation (10) represents a general equation for the correction at any junction in terms of the corrections at other points and the mathematical breaks in continuity of the lines connecting the junction with the other points. Ordinarily, the Baldwin method has been used to determine the correction at a particular junction when the corrections at the other points have been known.

Extension of Baldwin Method.—The same principle may be applied to a more complicated level net, as indicated in Fig. 4. Denote the correction to any junction by the letter used to designate that junction; the weight of a line by the letter P and the subscript letters of the ends of the line; and the mathematical breaks in continuity in any line by the lower-case letters of the ends of the line, thus: The break or closure in B to D is bd, that in D to B is $db = -bd$, etc.

As A, E, H, and L are fixed points, their corrections are known from the closures at these points, and need not be computed. Equations similar to Equation (10) may be written for each of the remaining junctions. Thus, at B,

$$\begin{aligned} 0 = -(P_{ab} + P_{bd} + P_{bf})\,B + P_{ab}\,(A) + P_{bd}\,(D) + P_{bf}\,(F) \\ + P_{ab}\,(ab) + P_{bd}\,(db) + P_{bf}\,(fb) \end{aligned} \qquad (12)$$

If $P_{ab} + P_{bd} + P_{bf}$ (the sum of the weights of all lines entering junction B) is designated P_b, and $P_{ab}\,(ab) + P_{bd}\,(db) + P_{bf}\,(fb)$ (the sum of the products of the breaks of the lines into the junction by the weights of these lines) is designated Q_b, Equation (12) becomes

$$0 = -P_b\,(B) + P_{ab}\,(A) + P_{bd}\,(D) + P_{bf}\,(F) + Q_b \qquad (13)$$

Similarly, equations for the other junctions to be adjusted may be written as follows: At D,

$$0 = -P_d\,(D) + P_{bd}\,(B) + P_{de}\,(E) + P_{dg}\,(G) + Q_d \qquad (14)$$

at F,

$$0 = -P_f\,(F) + P_{bf}\,(B) + P_{fg}\,(G) + P_{fj}\,(J) + Q_f \qquad (15)$$

at G,

$$0 = -P_g\,(G) + P_{gk}\,(K) + P_{fg}\,(F) + P_{dg}\,(D) + Q_g \qquad (16)$$

at J,

$$0 = -P_j\,(J) + P_{hj}\,(H) + P_{fj}\,(F) + P_{jk}\,(K) + Q_j \qquad (17)$$

and, at K,

$$0 = -P_k\,(K) + P_{jk}\,(J) + P_{gk}\,(G) + P_{kl}\,(L) + Q_k \qquad (18)$$

As there are six unknown junction corrections and six equations, a rigid solution is possible.

Equations (13) to (18) may be written most conveniently by inspection in the form of a table, the unknown corrections being used to designate the columns, in which only the numerical coefficients need be placed (see Table 5).

If the equations are written in the same sequence as the columns, it will be seen that the negative terms form a diagonal, about which the table is symmetrical, except for the Q-column; that is, all coefficients to the left (or to the right) of any negative term appear again above (or below) it in the same relative position. Thus, except for the Q-column, the table may be read across or down with the same results. This symmetry makes it possible to condense the table by omitting all coefficients to the left of the "diagonal" terms. Then each equation is read down to its diagonal term and across through its absolute term.

In this form the equations may be solved readily by the Doolittle method[4] to give the required junction corrections (see Appendix II).

TABLE 5.—ADJUSTMENT EQUATIONS

At point:	B	D	F	G	J	K	Q
B	$-P_b$	$+P_{bd}$	$+P_{bf}$				$+Q_b$ $+P_{ab}$ (A)
D	$+P_{bd}$	$-P_d$		$+P_{dg}$			$+Q_d$ $+P_{de}$ (E)
F	$+P_{bf}$		$-P_f$	$+P_{fg}$	$+P_{fj}$		$+Q_f$
G		$+P_{dg}$	$+P_{fg}$	$-P_g$		$+P_{gk}$	$+Q_g$
J			$+P_{fj}$		$-P_j$	$+P_{jk}$	$+Q_j$ $+P_{hj}$ (H)
K				$+P_{gk}$	$+P_{jk}$	$-P_k$	$+Q_k$ $+P_{kl}$ (L)

This method of adjustment is not only suitable for levels, but it is even more advantageous in its application to a traverse net. Instead of a single closure error at each junction, a traverse survey has two closures—in latitude and in longitude, or in northing and easting. These two closures are considered independently and, in other methods of adjustment, require individual treatment. However, by the method presented herein, the equations for the corrections at any particular junction are identical except for the absolute or Q-terms. Thus, both sets of equations may be combined in a single table, similar to Table 5, but having two absolute columns—one for northing and one for easting. The effort required for the solution of both sets is only slightly greater than that required for one alone.

To provide a check on the formation and solution of the equations, an extra column is added to the table. The items in this column are dimensionless numbers, each being the sum of the coefficients and absolute terms of its equation. This sum column is not an essential part of the adjustment, but makes it possible to check each step before proceeding to the next.

APPENDIX II

SIMPLIFIED SOLUTION OF ADJUSTMENT EQUATIONS BY THE DOOLITTLE METHOD

The Doolittle method is a semi-mechanical method for solving simultaneous equations of the symmetrical type formed in this method of adjustment. It is much quicker than the regular algebraic solution, especially when there are many equations to be solved simultaneously, and is particularly adaptable to the use of a computing machine. By this method, as by others, the equations are combined successively, one of the unknowns being eliminated at each step. When all the equations have been combined, the resulting equation contains only one unknown, which may be evaluated readily. In the back solution, the evaluated unknowns are substituted successively back into the combined equations for the evaluation of the preceding unknowns.

In Tables 3 and 4, the original equations have been written on the *a*-lines, and each equation is read down its column to the diagonal term, then across through the absolute terms. The *b*-lines, in Table 4, contain the combined equations, each of which includes the influence of those preceding it. Because of the elimination of one additional unknown, each combined equation contains one term less than the preceding one. The combined equations, on the *b*-lines, are read straight across. The equations on the *c*-lines are mathematically identical with the corresponding *b*-equations, but they express the principal unknown as an explicit function of the remaining unknowns. The items on the *c*-lines are the multipliers to be used in the formation of the combined equations on the succeeding *b*-lines. It is obvious that in the first equation the *a*- and *b*-lines are identical and need be written only once.

The procedure for combining and solving the equations follows a few definite rules; when once mastered, it becomes almost mechanical and requires practically no mental effort. The method is best illustrated by completing the solution of the equations in Table 3. The complete solution is shown in Table 4.

The first step in the solution is the formation of Equation (1*c*) from Equation (1*b*). Equation (1) represents the correction at junction 1 in terms of the corrections at all other junctions; therefore the entry in Column (1) (the diagonal term of Equation (1*a*)) will be called the principal term of Equation (1*b*). Similarly, the *b*-item under each diagonal term will be called the principal term of its equation. To express the correction at junction 1 as an explicit function of the other corrections, its coefficient should be made − 1.0. This is done by multiplying all items on line 1*b* by the negative reciprocal of the principal term. The negative reciprocal (0.284657) of − 3.513 is entered, for convenience, in Column R at the left of the table and is multiplied by the items on line 1*b* to give the items shown on line 1*c*. Line 1*c* may now be checked by adding it across through the absolute columns, including − 1.0 for the first term, to equal the (S)-item, very nearly. A small difference may be due to the dropped residual decimals beyond the last significant figure. In general, the *c*-lines should be recorded to one decimal place more than the *b*-lines, in order to retain the same number of significant figures.

The next step in the solution is the formation of Equation (2*b*) by combining Equation (1*b*) with Equation (2*a*). In this step, everything to the left of Column (2) is ignored and each item in Equation (1*b*) is multiplied by the (1*c*)-term in Column (2); then it is added to the (2*a*)-item in its own column. Thus, Equation (2*b*) is formed as follows:

1*b*-2(+ 1.042) × 1*c*-2(+ 0.2966) + 2*a*-2(− 2.737) = 2*b*-2(− 2.428)
1*b*-3(0) × 1*c*-2(+ 0.2966) + 2*a*-3(+ 0.862) = 2*b*-3(+ 0.862)
1*b*-5(0) × 1*c*-2(+ 0.2966) + 2*a*-5(+ 0.833) = 2*b*-5(+ 0.833)
1*b*-N(+ 5.593) × 1*c*-2(+ 0.2966) + 2*a*-N(− 4.865) = 2*b*-N(− 3.206)
1*b*-E(+ 9.134) × 1*c*-2(+ 0.2966) + 2*a*-E(+ 0.367) = 2*b*-E(+ 3.076)
1*b*-S(+12.256) × 1*c*-2(+ 0.2966) + 2*a*-S(− 4.498) = 2*b*-S(− 0.863)

Each item is designated by its line and column, thus: Item 2*a*-3 is on line 2*a*, Column (3). Equation (2*b*) may now be checked by adding it across to equal its (S)-term, very nearly. Equation (2*c*) is formed from Equation (2*b*) in exactly the same manner as Equation (1*c*) was formed from Equation (1*b*). It is checked by adding it across from − 1.0 through the absolute columns to equal its (S)-term, as before.

Equations (1*b*), (2*b*), and (3*a*) are now combined to form Equation (3*b*). In this step, everything to the left of Column (3) is ignored, and the *c*-items in Column (3) are used as multipliers for their respective *b* equations. As there is no item in 1*c*-3 (giving a zero multiplier), Equation (1*b*) drops out of this step. Each item in Equation (2*b*) is multiplied by item 2*c*-3 and then added to the (3*a*)-item in its own column to form Equation (3*b*).

Equation (3*b*) is added across to check on its (S)-term. Equation (3*c*) is formed from Equation (3*b*), and checked. This same routine is followed throughout the forward solution. The first four equations are all short ones and are combined easily, as explained.

Equation (5*b*) is formed by combining Equations (1*b*), (2*b*), (3*b*), (4*b*), and (5*a*). In this step, everything to the left of Column (5), Table 4, is ignored, and the *c*-items in Column (5) are used as multipliers for their respective *b*-equations. As there is no item in 1*c*-5, Equation (1*b*) drops out of this step. To compute an item in any column on line 5*b*, multiply each *b*-item in the column by the *c*-item of its equation in Column (5), and add the products to the (5*a*)-item above the term being computed, thus:

$$\begin{aligned}
2b\text{-}5 \times 2c\text{-}5 + 3b\text{-}5 \times 3c\text{-}5 + 4b\text{-}5 \times 4c\text{-}5 + 5a\text{-}5 &= 5b\text{-}5\\
4b\text{-}6 \times 4c\text{-}5 &= 5b\text{-}6\\
2b\text{-N} \times 2c\text{-}5 + 3b\text{-N} \times 3c\text{-}5 + 4b\text{-N} \times 4c\text{-}5 + 5a\text{-N} &= 5b\text{-N}\\
2b\text{-E} \times 2c\text{-}5 + 3b\text{-E} \times 3c\text{-}5 + 4b\text{-E} \times 4c\text{-}5 + 5a\text{-E} &= 5b\text{-E}\\
2b\text{-S} \times 2c\text{-}5 + 3b\text{-S} \times 3c\text{-}5 + 4b\text{-S} \times 4c\text{-}5 + 5a\text{-S} &= 5b\text{-S}
\end{aligned}$$

always using the *c*-items in Column (5) as the multipliers for the corresponding *b*-items in the other columns. Equation (5*b*) is now checked by adding across to 5*b*-S. Equation (5*c*) is formed by multiplying Equation (5*b*) by the negative reciprocal of its principal term, and is checked by adding across, including the − 1.0, to equal 5*c*-S, very nearly. Equation (6*b*) is formed by combining the previous *b*-equations with Equation (6*a*) as already explained, and is checked on 6*b*-S.

Back Solution.—The same routine is followed to the formation and check of Equation (8*c*), which expresses the correction at junction 8 as an explicit function of no other unknown. In other words, the corrections at junction 8 appear in the absolute columns on line 8*c*, and are − 5.1507 in northing and − 5.1115 in easting. As the first unknowns evaluated, these are entered on lines CN and CE, respectively, in Column (8) of the back solution. To provide a check, 8c-S is entered in CS-8. Then, in Column (8), CN + CE − 1.0000 should equal CS, very nearly. (This check was already applied on line 8c.)

The corrections at junction 7 may be evaluated next. Equation (7c) expresses each correction at junction 7 as an explicit function of the corresponding correction at junction 8, which is already known. The corrections at junction 8 (which will be called, collectively, C8) are therefore substituted into Equation (7c) to evaluate C7. As these corrections, in reality, are independent variables, it will be necessary, in the back solution, to substitute them separately, and to evaluate but one correction at a time. Thus:

$$\text{CN-8} \times 7c\text{-8} + 7c\text{-N} = \text{CN-7}$$
$$\text{CE-8} \times 7c\text{-8} + 7c\text{-E} = \text{CE-7}$$

and,

$$\text{CS-8} \times 7c\text{-8} + 7c\text{-S} = \text{CS-7}$$

The (CS)-item is not a correction but is used as a check on the others and is computed in the same manner. For the check, as before, CN-7 + CE-7 − 1.0000 = CS-7. Similarly, C6 is computed by substituting C7 and C8 into Equation (6c), and is checked by adding CN, CE, and − 1.0000 to equal CS, very nearly. Thus:

$$\text{CN-7} \times 6c\text{-7} + \text{CN-8} \times 6c\text{-8} + 6c\text{-N} = \text{CN-6}$$
$$\text{CE-7} \times 6c\text{-7} + \text{CE-8} \times 6c\text{-8} + 6c\text{-E} = \text{CE-6}$$

and,

$$\text{CS-7} \times 6c\text{-7} + \text{CS-8} \times 6c\text{-8} + 6c\text{-S} = \text{CS-6}$$

In like manner, all evaluated corrections are substituted successively into the next preceding *c*-equation for the evaluation of the corrections at the next preceding junction. The same check is applied to all; namely, CN + CE − 1.0000 = CS. Note that in Equation (5c) there are no items in Columns (7) and (8); C7 and C8, therefore, do not enter into the computation of C5, as their multipliers are zero. Similar conditions are found throughout the remainder of the back solution, materially reducing the labor required for this part of the problem. When all the corrections have been computed and checked, back to C1, they are entered on the diagram on Fig. 1, as already explained.

DISCUSSION

George H. Dell,[5] **Assoc. M. Am. Soc. C. E.** (by letter).—A clear and interesting description of a simplified adaptation of the junction point method to the adjustment of level and traverse nets is presented in this paper. It may be worth noting that the results given by this method are identical with those obtained by basing the adjustment upon appropriate circuit-closure and route-closure conditions. It should also be observed that in applying the junction point method it is necessary that at least one point in the net be treated as a fixed point, or otherwise an indeterminate system of equations will result.

Fig. 5.—Latitude Adjustments

The Doolittle method of solving the normal equations is unexcelled for use in offices where the execution of intricate adjustments is a major occupation. In fact, axisymmetrical systems of equations are so frequently encountered in various branches of engineering that it would be highly desirable to include the Doolittle method in the mathematics requirements of all engineering students.

---

[5] Associate in Civ. Eng., Univ. of Illinois, Urbana, Ill.

For organizations or individuals having to deal only occasionally with adjustments of the type under discussion, or for classroom work where an adequate supply of computing machines may not be available, the solution of the equations by successive convergence, with slide rule, offers a satisfactory substitute for the more precise Doolittle method. Such a solution is illustrated in Fig. 5, which deals with the latitude corrections in the example given by the authors. The absolute term at each junction is shown within a square, followed by the sum of the weights, ΣP. In the first cycle, the absolute terms, augmented by corrections carried over from adjacent junction points, are distributed toward these junction points in proportion to the weights of the connecting lines. In succeeding cycles, only the preceding set of corrections are brought over and distributed. In each cycle the sequence of adjustment follows that of the authors' equations.

the distribution toward junctions 1, 3, and 5 being − 1.22, − 1.01, and − 0.97, respectively. Similarly, at junction 3, the quantity to be distributed is − 1.01 + 0.00, or − 1.01, of which $\frac{0.862}{3.80}$ (= − 0.23) and $\frac{0.769}{3.80}$ (= − 0.20) are distributed toward junctions 2 and 4, respectively. A complete list of the quantities to be distributed is given in Table 6, and it is seen that after 4½ cycles all equations have begun to converge consistently. The fifth set of corrections in Fig. 5 is the result of series summations, obtained by multiplying the fourth set of corrections by the summation factor, which is found as follows: The absolute sum of the last set of eight quantities in Table 6 (= 1.67) was divided by the absolute sum of the preceding eight quantities (= 3.59), giving 0.465 as the average rate of convergence, r. The summation factor, $\frac{r}{1-r}$, therefore, is 0.87. The final values shown in Fig. 5 are the unknowns of the adjustment equations and are obtained by dividing the sums of the various columns by the weights of the corresponding lines.

With regard to the opening paragraph of the authors' "Conclusion," the writer agrees that mathematical inconsistencies should be eliminated by adjustment, and that careful surveys are thereby improved. The writer, however, is inclined to guard against placing undue reliance on such improvement, and believes that a high standard of precision can best be insured by rigorous field work. The results of a least-squares adjustment depend largely upon the weights, and, in a quantitative sense, surveys of high order are much less seriously affected by errors in judging the weights than are surveys of relatively low order.

The traverse used by the authors has been analyzed by the writer with a view to determining the effects of errors or variations in the weights. As a

basis for this study, use was made of expressions for the differentials of the unknowns of the normal equations with respect to the weights,[6] the calculations being based on hypothetical variations of 10% in the weights. The individual effects of these variations in weight are shown in Table 7, quantities of about 0.05 ft or greater being underlined, and the maximum combined effects being shown in the final line. For example, a 10% increase in the weights of lines *d* and *e* would produce corresponding changes of + 0.2366 ft and − 0.1590 ft, respectively, in the value of C_{1N}, and the maximum combined effect of such errors in all weights would be 0.5036 ft for this particular unknown.

Because of the complexity of the factors involved, it appears not unreasonable to suppose that, unless great care is taken, the inaccuracies in the assumed weights of some of the lines may be as great at 50%. The effects of variations greater than 10% in the weights would be approximately proportional to the quantities shown in Table 7. Therefore, it is seen that variations of 50% in the weights of certain individual lines would produce corresponding variations of from 0.25 ft to 1.00 ft or more instead of the underlined quantities, and the maximum combined effects of such errors or variations would range from 0.94 ft to 2.67 ft, approximately. However, if it were possible to limit the errors in the weights to the order of 10%, the corresponding errors in the final coordinates could not be materially in excess of 0.50 ft, and would probably be within 0.25 ft in most of the quantities.

It is thus seen that, in order to use the least-squares adjustment to best advantage as a means of improving the results of a low-order survey at a saving in field costs, it is desirable that great care should be exercised in determining the weights. Among the factors upon which the weight of a given line depends are: (*a*) The length of line, (*b*) the number of instrument stations or set-ups it contains, (*c*) the number of independent measurements (repetitions) entering into the data, (*d*) atmospheric conditions, (*e*) the character of the terrain, and (*f*) the quality of instruments and survey methods, including the personal equations or relative skilfulness of the various observers. It would appear that the development of a practical method of taking these factors into account in determining the weights would be a valuable step.

The authors are to be highly commended for presenting such a clear description of their improved junction point method and for their success in producing a really useful simplification of the method in question.

HOWARD S. RAPPLEYE,[7] M. AM. SOC. C. E. (by letter).—After all is said and done, what appears simplest to each individual is that with which he is most familiar. The method of adjustment proposed in the paper by Messrs. Norris and Speert undoubtedly appears to be simple to them because they are thoroughly familiar with it; yet the writer, who attempted to duplicate a previously completed adjustment of a simple level net by the new method, as a means of comparison, was not at all fully convinced that the statement (see "Conclusion")—"* * * if the instructions are observed carefully, a complete adjustment can be made by a clerk familiar with the use of the computing machine"—was not slightly overdrawn. Now that he has actually made an adjustment by the method, and has found that the results agreed within one unit in the last place with the results of the previous adjustment by another method, the writer can see that the proposed method has much to recommend it.

[6] *Bulletin No. 309*, Sections 7, 10, and 13, Univ. of Illinois Eng. Experiment Station, Urbana, Ill.

[7] Mathematician, U. S. Coast and Geodetic Survey, Washington, D. C.

Henry G. Avers, Assoc. M. Am. Soc. C. E., has presented[8] the complete adjustments of a level net, including six closed circuits and either one or two fixed elevations, solved by both the condition-equation and observation-equation methods. As a check on the method proposed by Messrs. Norris and Speert, this same net was adjusted by their method, and it was found that the resulting table of adjustment equations, except the "constant-term" and "check-sum" columns, was identical with that used in the observation-equation method[9] with all signs changed.

As to the relative speed of the various methods of adjustment, the writer is not yet sufficiently familiar with the Norris-Speert method to make an adequate comparison; but at present he fails to see any marked advantage of the proposed method over the older methods in this respect.

The fact that in the proposed method practically the same routine is used for the adjustment of both horizontal and vertical control surveys is an advantage. The routine is quite mechanical and, once one becomes familiar with the details of the procedure, little or no thought need be given to the underlying mathematics. A strict attention to algebraic signs, and care in the manipulation of the computing machine, should lead to excellent results.

However, the writer would like to caution any one who is attempting for the first time to adjust a traverse or level net by this method, and with no help other than the paper as printed, to select a small adjustment for practice purposes. Otherwise, failure to follow all the exacting detail may lead to erroneous results and eventual abandonment of a perfectly good method as being "too complicated."

In the writer's opinion a sample of a small level-net adjustment should have been included in the paper. He suggests that it be included in the closing discussion. It should be carried at least as far as the formation of the complete set of normal equations. An explanation of the application of the resulting corrections in the case of a level-net adjustment should also be included in order to make the paper more generally useful to those who may want to adjust levels as well as traverse.

R. M. WILSON,[10] M. AM. SOC. C. E. (by letter).—In 1927 a readjustment of the first-order triangulation net covering the United States was begun by the U. S. Coast and Geodetic Survey. The result changed, slightly, the geodetic coordinates for established triangulation stations throughout the country. Corrections to obtain proper agreement with the re-defined geodetic reference datum were thus imposed upon all dependent surveys which had used those stations before the readjustment.

[9] *Loc. cit.*, p. 73.

[10] Chf., Section of Computing, U. S. Geological Survey, Washington, D. C.

The U. S. Geological Survey had in its files the accumulated results of its own control surveys, consisting of triangulation done since 1879 and transit traverse done since 1899, all referred to the old North American Datum. Because of the great volume of records involved, it was a real problem to find an economical way to revise the results of these surveys to make them consistent with the new North American Datum of 1927. The scheme adopted to refer the older triangulation to the new datum has been described by Mr. Speert in another paper.[11]

The older transit traverse by the Geological Survey had been extended into areas far from supporting triangulation. Now, however, arcs of new triangulation by the Coast and Geodetic Survey pass through many areas where support for the older traverse was needed urgently. In 1936, an allotment of funds by the U. S. Public Works Administration made it possible to send out field parties to make ties between the older traverse and the new triangulation. Thus the results of the traverse required revision not only because of changes in the coordinates of triangulation stations from which the traverse was originally extended, but also because of the strengthened ties to new arcs of triangulation.

Generally the traverse in a local project was given simple line-by-line adjustment as soon as it was computed, and much of it was subsequently readjusted one or more times due to the influence of newer traverse in later adjacent projects. In order that the effect of these old and sometimes doubtful local adjustments may be eliminated in the general revision to the new datum, the separate lines or elements of the traverse net are now (1940) being taken from the records as originally computed, freed from the corrections of all previous adjustments. Then they can be fitted together again, simultaneously and upon equal terms, under the present conditions of stronger basic control.

A suitable and conventional method of least squares was already available when these general revision adjustments were begun about 1934. Elements of the net were assembled into groups until a convenient number of circuits were formed and condition equations, one for each circuit, were solved in the usual manner. The volume of work thus accomplished is indicated by the following data. The number of circuits in one solution usually was about fifteen, although a few contained as many as twenty-five, and one contained thirty-six. About 180 such solutions were completed, all together involving some 40,000 linear miles of transit traverse surveys.

Out of that background the Norris-Speert method emerged. Now it is the number of unfixed junction points involved, rather than the number of circuits, that determines the size of an individual solution. The elements to be adjusted are assembled into groups as before, but with about twenty equations preferred instead of fifteen; in two instances, groups containing more than fifty equations have been solved. Since 1938 about seventy-five of these solutions have been done, so that nearly 18,000 additional miles of traverse lines have been adjusted by the new method. Approximately 43% of the traverse done before the results of the 1927 triangulation adjustment were available still needs readjustment, however. The Norris-Speert method has been used also to adjust a large part of the new traverse work of the Geological Survey, at the rate of about 7,000 miles per yr. It will be seen, therefore, that the method has been fully tested in practice.

---

[11] "Readjustment of Triangulation Datum," by Julius L. Speert, *Transactions*, Am. Soc. C. E., Vol. 103 (1938), p. 1002.

The paper seems well written, and it is difficult to imagine how the ideas it contains could be more clearly expressed. Nevertheless, to one familiar with the computation there comes a feeling of regret that a really simple routine should be so masked, by the necessity of conveying it in print, as possibly to hide its simplicity from any one not having the perseverance to feel his way through it the first time.

The basic principle, which can be grasped readily by any one familiar with elementary algebra, is stated in the third paragraph of Appendix I thus: "* * * the adjusted elevation of bench mark *D* is to be a weighted mean of the elevations brought in through the various lines tying to it." This is easy to achieve if the "lines tying to it" all come from points whose elevations are fixed and known. The condition may be expressed as a simple algebraic equation. If a line comes from another point (called *G*, perhaps), where the elevation is not known, the equation can still be written for the elevation of *D* by including the elevation of *G* as an unknown. Another equation can then show the elevation of *G* with the elevation of *D* as an unknown. Then these two simple algebraic equations can be solved simultaneously for the unknown elevations at the two points *D* and *G*. Extending this principle, simultaneous equations, properly weighted, can be written for all unadjusted junction points of a complicated net. Solving them, the elevation determined at each junction will then be "* * * a weighted mean of the elevations brought in through the various lines tying to it." That principle is the important disclosure; the remainder of the paper is a description of the computing forms and routines as used by the Geological Survey to apply the principle efficiently in practice.

CLEVELAND B. COE,[12] ASSOC. M. AM. SOC. C. E. (by letter).—In presenting a method that may be used by any surveyor, to adjust the results of his work, the authors of this paper are to be commended greatly. Unfortunately, it is true that surveyors and designers alike tend to "shy away" from anything that suggests higher mathematics, and the name "least squares" is something to terrify the unwary. Consequently, the presentation of a simplified method

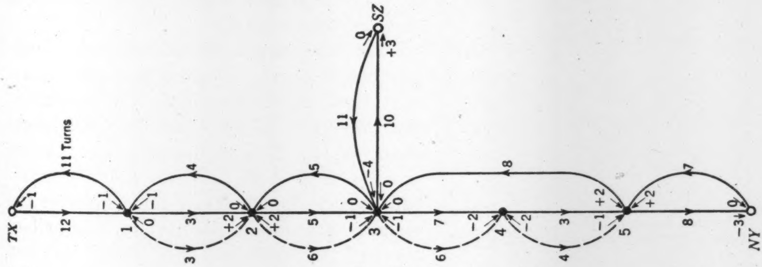

FIG. 6

---

[12] Associate Highway Engr. (TVA), Chattanooga, Tenn.

is a genuine service to the profession. The writer searched many texts without success for a simple method of adjustment for a series of interlocking traverses in connection with a fairly extensive contour survey of the town of Norris, Tenn., and the Norris-Speert presentation would have been extremely welcome.

* Fixed bench mark.

Inasmuch as the application given in the paper is to traverse closures, the writer feels that the paper would be made more valuable to the average engineer by an example of adjustment in a very simple and typical case of levels run to establish bench marks along a surveyed route. For this purpose consider the notes in Table 8, reduced from a series of level lines. This is the common case of running from one fixed bench mark, closing on another, and establishing between them a number of new marks; then running back, turning on each mark, and closing on the original. A third set of readings is provided when the cross sections are taken and an additional tie to a third fixed bench mark also enters the adjustment. For clearness, the field procedure and closure results are shown in Fig. 6. For convenience, the closure results, originally in hundredths of a foot, are shown as integers. The elevations obtained by the first line run (shown in Fig. 6 as straight) are taken as the basic elevations, to which any computed correction is to be applied. Therefore, all closures on this line are zero except the final closures on fixed bench marks.

The lines are weighted inversely as the number of turns. This is a reasonable assumption, as the foresights and backsights are presumed to be equal and not longer than 300 ft. It is assumed further that the cross-section levels are not taken as carefully as the bench levels and therefore the weights are made, arbitrarily, one half of those of the bench and check levels, as given in Table 9. These weights are obtained by setting 3 on the CI-scale of the slide rule over 1 on the D-scale and reading directly under each of the other number of turns.

The table is then filled out in accordance with the Norris-Speert method, following these general rules (see Table 4);

1. Fill in all *a*-lines:
    - 1*a*-1 Negative sum of all weights entering 1,
    - 1*a*-2 Sum of weights entering 2 from 1; and similarly for 2*a*-2, 2*a*-3, etc.
2. Fill in N-column:
    - 1*a*-N Sum (weights × net closures) entering 1; and similarly for 2*a*-N, etc.
    - Check: Sum (weights × net closures) entering fixed bench marks. Place this sum at the bottom of N-column and add all items in the column, which gives zero.
3. Fill in S-column:
    - 1*a*-S Negative sum of weights entering 1 from a fixed bench mark, plus 1*a*-N; and similarly for 2*a*-S, etc.
    - Check: 1*a*-S = sum of all entries in line 1*a*;
      2*a*-S = sum of all entries in line 2*a*, plus all in Column (2); and similarly for 3*a*-S, etc.

TABLE 9.—WEIGHTS APPLIED TO LEVEL NOTES

Levels	Weights, for the Following Number of Turns:

b								
c								
							−0.02	

This completes the original entries in the table and the results are shown in Table 10.

The problem is then solved by the Doolittle method in accordance with the following general rules (see Table 11):

1. 1*b*-R = negative reciprocal of 1*b*-1;

2. Multiply all entries in line 1*a* by 1*b*-R and enter results in line 1*c*;

3. 2*b*-2 = 1*b*-2 × 1*c*-2 + 2*a*-2;

4. If there are any other entries in line 1*b*, multiply them by 1*c*-2 and add to the next *a*-entry below to get the next *b*-entry;

5. 2*b*-R = negative reciprocal of 2*b*-2;

6. Any final *b*-entry is the sum of the products of all *b*-entries and *c*-entries above it, plus the last *a*-entry;

7. Repeat until table is complete;

8. All *b*-lines in column N are filled by multiplying all *b*-entries above by the *c*-entries in the column in question and adding the *a*-entry;

9. Similarly for the *b*-lines in column S;

10. Compute the *c*-entries in columns N and S—1*c*-N = 1*b*-N × 1*b*-R and 1*c*-S = 1*b*-S × 1*b*-R—and similarly for 2*c*-N, etc.; and

11. Check the *b*-lines and *c*-lines by adding across. The S-column is the sum of the other columns.

TABLE 11.—SOLUTION OF ADJUSTMENT EQUATIONS

Equation	R	(1)	(2)	(3)	(4)	(5)	N	S
(1) *ab*	+0.361	−2.77	+2.25				−1.75	−2.27
c		−1.0	+0.812				−0.632	−0.820
(2) *a*			−3.70	+1.45			+2.50	+2.50
